

AN ABSTRACT OF THE DISSERTATION OF

Jeffrey M. Young for the degree of Doctor of Philosophy in Computer Science
presented on May 28, 2021.

Title: Variational Satisfiability Solving

Abstract approved: _____

Eric Walkingshaw

Over the last two decades, satisfiability and satisfiability-modulo theory (SAT/SMT) solvers have grown powerful enough to be general purpose reasoning engines throughout software engineering and computer science. However, most practical use cases of SAT/SMT solvers require not just solving a single SAT/SMT problem, but solving sets of related SAT/SMT problems. This discrepancy was directly addressed by the SAT/SMT community with the invention of incremental SAT/SMT solving. However, incremental SAT/SMT solvers require end-users to hand write a program which dictates the terms that are shared between problems and terms which are unique. By placing the onus on end-users, incremental solvers couple the end-users' solution to the end-users' *exact* sequence of SAT/SMT problems—making the solution overly specific—and require the end-user to write extra infrastructure to coordinate or handle the results.

This dissertation argues that the aforementioned problems result from accidental complexity produced by solving a problem that is *variational* without the concept of

variation, similar to problematic use of GOTO statements in the absence of WHILE loop constructs. To demonstrate the argument, this thesis applies theory from *variational* programming to the domain of SAT/SMT solvers to create the first variational SAT solver and solve aforementioned problems. To do so, the thesis formalizes a variational propositional logic and specifies variational SAT solving as a compiler, which compiles variational SAT problems to non-variational SAT that are processed by an industrial strength SAT solver. It shows that the compiler is an instance of a variational fold and uses that fact to extend the variational SAT solver to an asynchronous variational SMT solver.

Chapter 1: Introduction

Controlling complexity is a central goal of any programming language, especially as software written in that language grows. The burgeoning field of *variation theory* and *variational programming* [38, 37, 47, 25, 86] attempt to control a kind of complexity which is induced into software when many *similar yet distinct* kinds of the same software must coexist. For example, software is often *ported* to other platforms, creating similar, yet distinct instances of that software which must be maintained. Such instances of variation are ubiquitous: Web applications are tested on multiple servers; programming languages maintain backwards compatibility and so do software libraries; databases evolve over time, locale and data; and device drivers must work with varying processors and architectures. Variation theory and variational programming have been successful in small systems, yet it has not been tested in a performance demanding practical domain. In the words of Joe Armstrong[3], “No theory is complete without proof that the ideas work in practice”; this is the project of this thesis, to put the ideas of *variation* and *variational programming* to the test in the practical domain of satisfiability solving (SAT).

cite variational data
structures and images

The major contribution of this thesis is the formalization of a *VPL*, *variational satisfiability solving*, and the construction of a *variational SAT solver*. In the next section I motivate the use of variation theory and variational techniques in satisfiability solving. In addition to work on variational SAT several other contributions are made. The thesis

extends variational satisfiability solving to variational SMT. It demonstrates reusable techniques and architecture for constructing *variational or variation-aware* systems using the non-variational counterparts of these systems for other domains. It shows that, with the concept of variation, the variational SMT and SAT solvers can be trivially parallelized. Lastly, the thesis provides a general algorithm to construct variational strings from a set of non-variational strings and argues for the proliferation of variation theory to other domains in computer science.

1.1 Motivation and Impact

Classic SAT, which solves the boolean satisfiability problem [14] has been one of the largest success stories in computer science over the last two decades. Although SAT solving is known to be NP-complete [28], SAT solvers based on conflict-driven clause learning (CDCL) [59, 75, 10] have been able to solve boolean formulae with millions variables quickly enough for use in real-world applications [82]. Leading to their proliferation into several fields of scientific inquiry ranging from software engineering to Bioinformatics [58, 42].

The majority of research in the SAT community focuses on solving a single SAT problem as fast as possible, yet many practical applications of SAT solvers [76, 74, 87, 17, 34, 32, 40] require solving a set of related SAT problems [74, 76, 32]. To take just one example, software product-lines (SPL) utilizes SAT solvers for a diverse range of analyses including: automated feature model analysis [11, 41, 79], feature model sampling [62, 83], anomaly detection [2, 52, 60], and dead code analysis [78].

This misalignment between the SAT research community and the practical use cases of SAT solvers is well known. To address the misalignment, modern solvers attempt to propagate information from one solving instance, on one problem, to future instances in the problem set. Initial attempts focused on clause sharing (CS) [74, 87] where learned clauses from one problem in the problem set are propagated forward to future problems. Although, modern solvers are based on a major breakthrough that occurred with *incremental SAT under assumptions*, introduced in Minisat [33].

Incremental SAT under assumptions, made two major contributions: a performance contribution, where information including learned clauses, restart and clause-detection heuristics are carried forward. A usability contribution; Minisat exposed an interface that allowed the end-user to directly program the solver. Through the interface the user can add or remove clauses and dictate which clauses or variables are shared and which are unique to the problem set, thus directly addressing the practical use case of SAT solvers.

Despite its success, the incremental interface introduced a programming language that required an extra input, the set of SAT problems, *and* a program to direct the solver with side-effectual statements. This places further burden on the end-user: the system is less-declarative as the user must be concerned with the internals of the solver. A new class of errors is possible as the input program could misuse the introduced side-effectual statements. By requiring the user to direct the solver, the users' solution is specific to the exact set of satisfiability problems at hand, thus the programmed solution is specific to the problem set and therefore to the solver input. Should the user be interested in the assignment of variables under which the problem at hand was found to

be satisfiable, then the user must create additional infrastructure to track results; which again couples to the input and is therefore difficult to reuse.

We argue that solving a set of related SAT problems *is a variational programming problem* and that by directly addressing the problem's variational nature the incremental SAT interface and performance can be improved. The essence of variational programming is a formal language called the *choice calculus*. With the choice calculus, sets of problems in the SAT domain can be expressed syntactically as a single *variational artifact*. The benefits are numerous:

1. The side-effectual statements are hidden from the user, recovering the declarative nature of non-incremental SAT solving.
2. Malformed programs built around the control flow operators become syntactically impossible.
3. The end-user's programmed solution is decoupled from the specific problem set, increasing software reuse.
4. The solver has enough syntactic information to produce results which previously required extra infrastructure constructed by the end-user.
5. Previously difficult optimizations can be syntactically detected and applied before the runtime of the solver.

This work is applied programming language theory in the domain of satisfiability solvers. Due to the ubiquity of satisfiability solvers estimating the impact is difficult although the surface area of possible applications is large. For example, many analyses

in the software product-lines community use incremental SAT solvers. By creating a variational SAT solver such analyses directly benefit from this work, and thus advance the state of the art. For researchers in the incremental satisfiability solving community, this work serves as an avenue to construct new incremental SAT solvers which efficiently solve classes of problems that deal with variation.

For researchers studying variation the significance and impact is several fold. By utilizing results in variational research, this work adds validity to variational theory and serves as an empirical case study. At the time of this writing, and to my knowledge, this work is the first to directly use results in the variational research community to parallelize a variation unaware tool. Thus by directly handling variation, this work demonstrates direct benefits to be gained for researchers in other domains and magnifies the impact of any results produced by the variational research community. Lastly, the result of my thesis, a variational SAT solver, provides a new logic and tool to reason about variation itself.

1.2 Contributions and Outline of this Thesis

The high-level goal of this thesis is to use variation theory to formalize and construct a variational satisfiability solver that understands and can solve SAT problems that contain *variational values* in addition to boolean values. It is our desire that the work not only be of theoretical interest but of practical use. Thus, the thesis provides numerous examples of variational SAT and variational SMT problems to motivate and demonstrate the solver. The rest of this section outlines the thesis and expands on the contributions

of each chapter:

1. [Chapter 2](#) (*Background*) provides the necessary material for a reader to understand the contributions of the thesis. This section provides an overview of satisfiability solving, satisfiability-modulo theories solving, incremental SAT and SMT solving . Several important concepts are introduced: The definition of satisfiability and definition of the boolean satisfiability problem. The internal data structure incremental SAT solvers utilize to provide incrementality, and the side-effectual operations which manipulate the incremental solver and form the basis of variational satisfiability solving. Lastly, the definition of the output of a SAT or SMT solver which has implications for variational satisfiability solving and variational SMT.
2. [Chapter 3](#) (*Variational Propositional Logic*) introduces a variational logic that a variational SAT solver operates upon. This section introduces the essential aspects of variation using propositional logic and in the process presents the first instance of a *variational system recipe* to construct a *variation-aware* system using a non-variational version of that system. Several variational concepts are defined and formalized which are used throughout the thesis, such as *variant*, *configuration* and *variational artifact*. Lastly, the section proves theorems that are central to proof of the soundness of variational satisfiability solving.
3. [Chapter 4](#) (*Variational Satisfiability Solving*) makes the central contribution of the thesis. In this chapter we define the general approach and architecture of a variational satisfiability solving. The general approach is the second presentation of

the aforementioned recipe; in this case using a SAT solver rather than propositional logic. This section provides a rationale for this design and makes several important contributions:

- (a) An operational semantics of variational satisfiability solving. A variational SAT problem is a description of the problem in variational propositional logic that is translated to an incremental SAT program which is suitable for execution on an incremental SAT solver.
 - (b) A formal definition of concepts such as a *variational core* which are transferable to domains other than SAT. Variational cores are instances of var
 - (c) A definition of a *variational transpiler*. The transpiler is defined as a variational fold which is the basis for the performance gains presented in the thesis. The folding algorithm is defined in three phases to ensure that non-variational terms are shared across SAT problems and thus redundant computation is mitigated.
 - (d) A definition of a variational output that is returned to the user. The output presents several unique challenges that must be overcome while still being useful for the end user. We present and consider these concerns and provide a salable solution.
4. [Chapter 5](#) (*Variational Satisfiability-Modulo Theory Solving*) extends the variational solving algorithm to consider SMT theories and propositions which include numeric values such as Integers and Reals in addition to Booleans. We present the requisite extensions to the variational propositional logic, the variational com-

pilers and solving algorithm, and extend the output to support types other than just Booleans. We demonstrate that our method fully generalizes to the core SMT theories in the SMTLIB2 standard.

5. [Chapter 6](#) (*Case Studies*) The central project of this thesis is to evaluate the ideas of variational programming in satisfiability solving. Having defined and constructed a variational SAT and SMT solver in the previous chapters this chapter empirically evaluates the solvers. The first section demonstrates performance improvements in variational SAT's intended use case. The second section presents variational versions of classic SAT problems such as: ... and serves as a tutorial for identifying, writing, and solving variational SAT problems with a variational SAT solver.

fill after making examples

6. [Chapter 7](#) (*Related Work*) is split into two sections. First, this thesis is situated into a lineage of recent variational-aware systems, thus this section collects this research and provides a comparison of our method to create a variational-aware system with previous methods. Second, this work is related to numerous SAT solvers that attempt to reuse information, solve sets of SAT problems and implement incremental SAT solving. We situate this work in the context of these solvers and compare their methods.

7. [Chapter 8](#) (*Conclusion and Future Work*) summarizes the contributions of the thesis and relates the work to the central project of the thesis. In addition to the conceptual point, numerous areas of future work are discussed; from further variational extensions to faster implementation strategies and novel application do-

not sure how to write this one yet

Chapter 2: Background

This section provides background on SAT and incremental SAT solving. It is intended as a general introduction to these concepts. Specific techniques or algorithms are not discussed in detail. All descriptions follow the SMT-LIB2 [9] standard and describe incremental solvers as a black box eliding internal details of any specific solver which adheres to the standard.

2.1 SMTLIB2 and Satisfiability Solving

This section provides assumes knowledge of propositional logic, and provides background to satisfiability solving and SMTLIB2 (smtlib); the standardized language for interacting with SAT solvers. Following the notation from the many-valued logic community [71] we refer to propositional logic as C_2 , which denotes a two-valued logic.

A satisfiability solver is a software system that solves the Boolean Satisfiability Problem [72]. One of the oldest problems in computer science¹ and famously NP-complete [28], the Boolean satisfiability problem is the problem of determining if a formula (sometimes called a sentence) in propositional logic has an assignment of Boolean values to variables, such that under substitution the formula evaluates to \top . We formalize the problem and terms in the following definitions:

¹see Biere et al. [15] for a complete history from the ancients, through to George Boole to the modern day.

Definition 2.1.1 (Model). Given a formula in propositional logic: $f \in C_2$, which contains a set of Boolean variables vs . A model, m , is a set of assignments of Boolean values to variables in f such that f evaluates to \mathbb{T} , i.e., $m = \{(v := b) \mid v \in vs, b \in \mathbb{B}\}$.

Corollary 2.1.0.1 (Validity). In propositional logic a formula or sentence is valid if it is true in all possible models [72]. That is, a valid formula or sentence is also a tautology.

not sure if this is the right place

Definition 2.1.2 (Satisfiable). Given a formula in propositional logic, f , which contains a set of Boolean variables vs . If there exists an assignment of variables to Boolean values such that f evaluates to \mathbb{T} , then we say f is *satisfiable*.

For example, we can show that the formula $good = (a \wedge b) \vee c$ is satisfiable with the model: $\{(a := \mathbb{T}), (b := \mathbb{T}), (c := \mathbb{F})\}$, because $(\mathbb{T} \wedge \mathbb{T}) \vee \mathbb{F}$ results in \mathbb{T} . However, a formula such as $bad = (a \vee b) \wedge \mathbb{F}$ is not satisfiable as no assignment of \mathbb{F} or \mathbb{T} to the variables a and b would allow bad to evaluate to \mathbb{T} . With the preliminaries concepts we can now define the Boolean Satisfiability Problem:

Definition 2.1.3 (Boolean Satisfiability Problem). Given a formula in propositional logic, f , determine if f is satisfiable.

While the formal definition of the Boolean Satisfiability Problem requires a formula in propositional logic, expressing a SAT problem in propositional logic can be cumbersome. Thus, modern satisfiability solvers programming languages to express SAT problems, communicate the problems to other people and dictate the problems to the solver. In recent years these programming languages have coalesced into a single standard via an international initiative called SMTLIB2.

The SMTLIB2 [9] standard formalizes a set of programming languages that define interactions with a SAT or SMT solver. The standard defines four languages, of which only two are used throughout this thesis: a *term* language; which defines a language for defining variables, functions and formulas in propositional and first-order logic. The *command* language; which defines a programming language to interact with the solver. The command language is used to add or remove formulas, query the solver for a model or check for satisfiability and other side-effectual interactions such as printing output.

For the remainder of this section we provide informal examples intended for a general audience and cover only the commands and concepts required for subsequent sections of this thesis. For a full language specification please see Barrett et al. [9].

define a listing language for smtlib

Consider this SMTLIB2 program which verifies peirce's law implies the law of ex-

cluded middle for propositional logic:

```

(declare-const a Bool)                ;; variable declarations
(declare-const b Bool)
(define-fun ex-middle ((x Bool)) Bool  ;; excluded middle:  $x \vee \neg x$ 
  (or x
    (not x)))
(define-fun peirce ((x Bool) (y Bool)) Bool ;; peirce's law:  $((x \rightarrow y) \rightarrow x) \rightarrow x$ 
  (=>
    (=> (=> x y)
      x)
    x))
(define-fun peirce-implies-ex-middle () Bool
  (=> (peirce a b)
    (ex-middle a)))
(assert (not peirce-implies-ex-middle)) ;; add assertion
(check-sat)                             ;; check SAT of all assertions

```

Comments begin with a semi-colon (;) and end at a new line. The program, and every SMTLIB2 program, is a sequence of *commands* (called *statements* in the programming

language literature) that interact with the solver. For example, the above program consists of five commands, two variable declarations, a function definition, an assertion and a command to check satisfiability. Each command is formulated as an *s-expressions* [61] to simplify parsing. For our purposes, one only needs to understand that commands and functions are called by opening parentheses; the first element after the opening parenthesis is the name of the command or function symbol and every other element is an argument to that command. Thus `(declare-const a Bool)` is an s-expression with three elements that defines the C_2 variable `a` of *sort* (called *type* in programming language literature) `Bool`. The first element, `declare-const` is the command name, the second is the user defined name for the variable and the third is its sort. Similarly, the s-expression `(and a b)` passes the variables `a` and `b` to the function and which returns the conjunction of these two variables. Lastly, the function definition `define-fun` takes four arguments: the user defined name; `peirce-is-ex-middle`, an s-expression that defines argument names and their sorts; `((x Bool) (y Bool))`, a return sort; `Bool` and the body of the function.

Internally, a compliant solver such as `z3` [29] maintains an stack called the *assertion stack* that tracks user provided variable and formula declarations and definitions. The elements of the assertion stack are called *levels* and are sets of *assertions*. An assertion is a logical formula, a declaration of a sort, or a definition of a function symbol. In the example, both variable declarations and the `peirce-is-ex-middle` definition are included in the assertion set. Sets of assertions are placed on the stack via the `assert` command. The `assert` command takes a term as input², collects all associated definitions and declarations and places the assertion set on the assertion stack.

²by the standard this is a *well-sorted term* of type *Bool*, however we elide this description for simplicity

The example demonstrates a common verification pattern in SAT and SMT solving. In the example, we construct a constraint that asserts (not peirce-is-ex-middle) rather than peirce-is-ex-middle because we need to verify that peirce’s law implies the law of excluded middle for all possible models. Had we elided the not then the first model which satisfied the theorem would be returned, thus providing a *single* model where the theorem holds. However, to prove the theorem we need to show that it holds *for all* possible models. The not negates the theorem thus asking the solver to discover a counter-example to the theorem. If such a model exists, then the solver has discovered a counter-example to the theorem. If no such model exists—that is UNSAT is returned by the solver—then the negated theorem always evaluates to F and thus the theorem always evaluates to T and hence is logically valid.

Satisfiability and logical validity are closely related. Conceptually, satisfiability attempts to find a model that solves the constraints of a formula, while logical validity tries to show that the formula’s truth-value is independent of it’s variables and thus the formula is tautological. Similarly, where satisfiability is concerned with solving constraints, validity is concerned with finding a proof. Thus it is common to negate a formula to *query* the solver to search for a counter-example, when no such model is found and UNSAT is returned, we can be sure that the negation of a formula which is always F is a formula which is always T, and thus is logically valid.

2.2 Incremental Satisfiability Solving

Suppose, we have three related propositional formulas that we desire to solve.

Figure 2.1

$$p = a \wedge b \wedge c \wedge e \quad q = a \wedge (b \vee \neg i) \wedge c \wedge (g \rightarrow c) \quad r = z \leftrightarrow (a \wedge b \wedge c \wedge e)$$

p is simply a conjunction of variables. In q , relative to p , we see that two variables are added, i , g , e is removed, and there are two new clauses: $(b \vee \neg i)$ and $(g \rightarrow c)$, both of which possibly affect the values of b and c . In r , the variables and constraints introduced in p are further constrained to a new variable, z .

Suppose one wants to find a model for each formula. Using a non-incremental SAT solver results in the procedure illustrated in Fig. 2.1a; where SAT solving is a batch process and no information is reused. Alternatively, a procedure using an incremental

SAT solver is illustrated in [Fig. 2.1b](#); in this scenario, all formulas are solved by single solver instance where terms are programmatically added or removed from the solver.

The ability to add and remove terms is enabled by manipulating the *assertion stack*. The previous example demonstrated a single level on the stack, this example demonstrates three. The incremental interface provides two new commands: `PUSH` to create a new variable *scope* and add a level to the stack and `POP` to remove the level. The following program follows the procedure outlined in [Fig. 2.1b](#) and solves p , q and r :

```

(declare-const a Bool)      ;; variable declarations for p
(declare-const b Bool)
(declare-const c Bool)
(declare-const e Bool)
(assert a)                  ;; a is shared between p and q
(push)                      ;; solve p
  (assert e)
  (assert c)
  (assert b)
  (check-sat)               ;; check-sat on p
(pop)                      ;; remove e, c, and b assertions
(push)                      ;; solve for q
  (declare-const i Bool)    ;; new variables
  (declare-const g Bool)
  (assert (or b (not i)))   ;; new clause
  (assert c)                ;; re-add c
  (assert (= g c))          ;; new clause
  (check-sat)               ;; check sat of q
(pop)                      ;; i and g out of scope
(reset)                    ;; reset the assertion stack
(declare-const a Bool)      ;; variable declarations for r
(declare-const b Bool)
(declare-const c Bool)
(declare-const e Bool)
(declare-const z Bool)
(assert (= z (and a (and b (and c (and e ))))))
(check-sat)                 ;; check-sat on r

```

In this example we begin by defining p , we assert a outside of a new scope so that it can be reused for q . We reuse a by exploiting the conjunction of assertions per level on the assertion stack during a CHECK-SAT call. Had we asserted (and a (and b (and c (and e)))) then we would not be able to reuse the assertion on a . The first PUSH command enters a new level on the assertion stack, the remaining variables are asserted and we issue a check-sat call. After the POP command, all assertions and declarations from the previous level are removed. Thus, after we solve q the variables i and g cannot be referenced as they are no longer in scope.

In an efficient process one would initially add as many *shared* terms as possible, such as a from p and then reuse that term as many times as needed. Thus, an efficient process should perform only enough manipulation of the assertion stack as required to reach the next SAT problem of interest from the current one. However, notice that doing so is not entirely straight forward; we were only able to reuse a from p in q because we defined p in a non-intuitive way by utilizing the internal behavior of the assertion stack. This situation is exacerbated by SAT problems such as r where due to the equivalence we were forced to completely remove everything on the stack in order to construct r . Thus incremental SAT solvers provide the primitive operations required to solve related SAT problems efficiently, yet writing the SMTLIB2 program to solve the set efficiently is not straightforward.

this is motivation but seems like a good time to make this point?

Chapter 3: Variational Propositional Logic

In this chapter, we present the logic of variational satisfiability problems. The logic is a conservative extension of classic two-valued logic (C_2) with a *choice* construct from the choice calculus [37, 85], a formal language for describing variation. We call the new logic VPL, short for variational propositional logic, and refer to VPL expressions as *variational formulas*. This chapter defines the syntax and semantics of VPL and concludes with a set of definitions, lemmas and theorems for the logic.

3.1 Syntax

The syntax of variational propositional logic is given in Fig. 3.1a. It extends the propositional formula notation of C_2 with a single new connective called a *choice* from the choice calculus. A choice $D\langle f_1, f_2 \rangle$ represents either f_1 or f_2 depending on the Boolean value of its *dimension* D . We call f_1 and f_2 the *alternatives* of the choice. Although dimensions are Boolean variables, the set of dimensions is disjoint from the set of variables from C_2 , which may be referenced in the leaves of a formula. We use lowercase letters to range over variables and uppercase letters for dimensions.

The syntax of VPL does not include derived logical connectives, such as \rightarrow and \leftrightarrow . However, such forms can be defined from other primitives and are assumed throughout the thesis.

$t ::=$	$r \mid \mathsf{T} \mid \mathsf{F}$	<i>Variables and Boolean literals</i>
$f ::=$	t	<i>Terminal</i>
	$\neg f$	<i>Negate</i>
	$f \vee f$	<i>Or</i>
	$f \wedge f$	<i>And</i>
	$D\langle f, f \rangle$	<i>Choice</i>

(a) Syntax of VPL.

$$\begin{aligned}
& \llbracket \cdot \rrbracket : f \rightarrow C \rightarrow \mathbb{B}_\perp \quad \text{where } C = D \rightarrow \mathbb{B}_\perp \\
& \llbracket t \rrbracket_C = t \\
& \llbracket \neg f \rrbracket_C = \neg \llbracket f \rrbracket_C \\
& \llbracket f_1 \wedge f_2 \rrbracket_C = \llbracket f_1 \rrbracket_C \wedge \llbracket f_2 \rrbracket_C \\
& \llbracket f_1 \vee f_2 \rrbracket_C = \llbracket f_1 \rrbracket_C \vee \llbracket f_2 \rrbracket_C \\
& \llbracket D\langle f_1, f_2 \rangle \rrbracket_C = \begin{cases} \llbracket f_1 \rrbracket_C & C(D) = \text{true} \\ \llbracket f_2 \rrbracket_C & C(D) = \text{false} \\ D\langle \llbracket f_1 \rrbracket_C, \llbracket f_2 \rrbracket_C \rangle & C(D) = \perp \end{cases}
\end{aligned}$$

(b) Configuration semantics of VPL.

$D\langle f, f \rangle \equiv f$	IDEMP
$D\langle D\langle f_1, f_2 \rangle, f_3 \rangle \equiv D\langle f_1, f_3 \rangle$	DOM-L
$D\langle f_1, D\langle f_2, f_3 \rangle \rangle \equiv D\langle f_1, f_3 \rangle$	DOM-R
$D_1\langle D_2\langle f_1, f_2 \rangle, D_2\langle f_3, f_4 \rangle \rangle \equiv D_2\langle D_1\langle f_1, f_3 \rangle, D_1\langle f_2, f_4 \rangle \rangle$	SWAP
$D\langle \neg f_1, \neg f_2 \rangle \equiv \neg D\langle f_1, f_2 \rangle$	NEG
$D\langle f_1 \vee f_3, f_2 \vee f_4 \rangle \equiv D\langle f_1, f_2 \rangle \vee D\langle f_3, f_4 \rangle$	OR
$D\langle f_1 \wedge f_3, f_2 \wedge f_4 \rangle \equiv D\langle f_1, f_2 \rangle \wedge D\langle f_3, f_4 \rangle$	AND
$D\langle f_1 \wedge f_2, f_1 \rangle \equiv f_1 \wedge D\langle f_2, \mathsf{T} \rangle$	AND-L
$D\langle f_1 \vee f_2, f_1 \rangle \equiv f_1 \vee D\langle f_2, \mathsf{F} \rangle$	OR-L
$D\langle f_1, f_1 \wedge f_2 \rangle \equiv f_1 \wedge D\langle \mathsf{T}, f_2 \rangle$	AND-R
$D\langle f_1, f_1 \vee f_2 \rangle \equiv f_1 \vee D\langle \mathsf{F}, f_2 \rangle$	OR-R

(c) VPL equivalence laws.

Figure 3.1: Formal definition of VPL.

3.2 Semantics

Conceptually, a variational formula represents several propositional logic formulas at once, which can be obtained by resolving all of the choices. For software product-line researchers, it is useful to think of VPL as analogous to `#ifdef`-annotated C_2 , where choices correspond to a disciplined [56] application of `#ifdef` annotations. From a logical perspective, following the many-valued logic of Kleene [51, 71], the intuition behind VPL is that a choice is a placeholder for two equally possible alternatives that is deterministically resolved by reference to an external environment. In this sense, VPL deviates from other many-valued logics, such as modal logic [43], because a choice *waits* until there is enough information in an external environment to choose an alternative (i.e., until the formula is *configured*).

The *configuration semantics* of VPL is given in Fig. 3.1b and describes how choices are eliminated from a formula. The semantics is parameterized by a *configuration* C , which is a partial function from dimensions to Boolean values. The first four cases of the semantics simply propagate configuration down the formula, terminating at the leaves. The case for choices is the interesting one: if the dimension of the choice is defined in the configuration, then the choice is replaced by its left or right alternative corresponding to the associated value of the dimension in the configuration. If the dimension is undefined in the configuration, then the choice is left intact and configuration propagates into the choice's alternatives.

If a configuration C eliminates all choices in a formula f , we call C *total* with respect to f . If C does *not* eliminate all choices in f (i.e., a dimension used in f is undefined

in C), we call C *partial* with respect to f . We call a choice-free formula *plain*, and call the set of all plain formulas that can be obtained from f (by configuring it with every possible total configuration) the *variants* of f .

To illustrate the semantics of VPL, consider the formula $p \wedge A\langle q, r \rangle$, which has two variants: $p \wedge q$ when $C(A) = \text{true}$ and $p \wedge r$ when $C(A) = \text{false}$. From the semantics, it follows that choices in the same dimension are *synchronized* while choices in different dimensions are *independent*. For example, $A\langle p, q \rangle \wedge B\langle r, s \rangle$ has four variants, while $A\langle p, q \rangle \wedge A\langle r, s \rangle$ has only two ($p \wedge r$ and $q \wedge s$). It also follows from the semantics that nested choices in the same dimension contain redundant alternatives; that is, inner choices are *dominated* by outer choices in the same dimension. For example, $A\langle p, A\langle r, s \rangle \rangle$ is equivalent to $A\langle p, s \rangle$ since the alternative r cannot be reached by any configuration. As the previous example illustrates, the representation of a VPL formula is not unique; that is, the same set of variants may be encoded by different formulas. Fig. 3.1c defines a set of equivalence laws for VPL formulas. These laws follow directly from the configuration semantics in Fig. 3.1b and can be used to derive semantics-preserving transformations of VPL formulas. For example, we can simplify the formula $A\langle p \vee q, p \vee r \rangle$ by first applying the OR law to obtain $A\langle p, p \rangle \vee A\langle q, r \rangle$, then applying the IDEMP law to the first argument to obtain $p \vee A\langle q, r \rangle$ in which the redundant p has been factored out of the choice.

3.3 Formalisms

Having defined the syntax and semantics of VPL the rest of this chapter will define useful functions and properties. We conclude the chapter with an example of encoding a set of C_2 formulas to a single VPL formula. First define useful functions to retrieve interesting aspects of VPL formulas.

Definition 3.3.1 (Dimensions). Given a formula $f \in \text{VPL}$, let $\text{Dimensions}(f)$ be the set of unique dimensions in the formula: $\text{Dimensions}(f) = \{D \mid D \in f\}$.

For example, $\text{Dimensions}(A\langle p, q \rangle \wedge B\langle r, s \rangle) = \{A, B\}$ and $\text{Dimensions}(A\langle p, q \rangle \wedge A\langle r, s \rangle) = \{A\}$. Similarly we define a notion of *cardinality* over VPL formulas.

Definition 3.3.2 (Dimension-cardinality). The dimension-cardinality or d-cardinality of a formula $f \in \text{VPL}$ is the cardinality of the set of unique dimensions in a formula. We use the following notation as shorthand: $|f|_D = |\text{Dimensions}(f)|$.

Similarly to *Dimensions* another useful function is *Variants*:

Definition 3.3.3 (Variants). Given a formula $f \in \text{VPL}$, let $\text{Variants}(f)$ be the set of all possible *plain variants* of f . Thus, $\text{Variants}(f) = \{v \mid \exists C. v = \llbracket f \rrbracket_C, v \in C_2\}$

Using *Dimensions* we can now define a more precise property on configurations.

Definition 3.3.4 (Valid Configuration). We say a configuration C is valid with respect to some formula $f \in \text{VPL}$ iff $\text{Dom}(C) \cap \text{Dimensions}(f) \neq \emptyset$.

One may think of a valid configuration as a total configuration with *nothing extra*. For example, the configuration $C = \{(A, \text{true}), (B, \text{false}), (E, \text{true})\}$ is total with

respect to the formula $f = A\langle p, q \rangle \wedge B\langle r, s \rangle$ because C eliminates all choices in f . However C is not valid with respect to f as $\text{Dom}(C) \cap \text{Dimensions}(f) = \{E\}$, and thus in this case C contains one extra binding for E , than needed with respect to f .

With these functions and definitions we can prove useful lemmas and theorems:

Theorem 3.3.1 (VPL reducible to C_2). *For any configuration C and any formula $f \in \text{VPL}$, if C is total with respect to f , then $\llbracket f \rrbracket_C \in C_2$*

Proof. This follows directly from the semantics of configuration in [Fig. 3.1b](#), and the definition of a total configuration. The proof is done by structural induction and case analysis; because C is total and the configuration semantic function is a total function, every choice and its' alternatives is recursively reified for f . Then by the definition of VPL a formula which lacks choices is $\in C_2$. \square

3.4 Example

To demonstrate the application of VPL and conclude the chapter, we encode the incremental example from [Chapter 2](#). Our goal is to construct a single variational formula that encodes the related plain formulas p , q , r . Ideally, this variational formula should maximize sharing among the plain formulas in order to avoid redundant analyses during a variational solving. We reproduce the formulas below for the convenience:

$$p = a \wedge b \wedge c \wedge e \quad q = a \wedge (b \vee \neg i) \wedge c \wedge (g \rightarrow c) \quad r = z \leftrightarrow (a \wedge b \wedge c \wedge e)$$

Every set of plain formulas can be encoded as a variational formula systematically

by first constructing a nested choice containing all of the individual variables as alternatives, then factoring out shared subexpressions by applying the laws in Fig. 3.1c. Unfortunately, the process of globally minimizing a variational formula in this way is hard¹ since we must apply an arbitrary number of laws right-to-left in order to set up a particular sequence of left-to-right applications that factor out commonalities.

Due to the difficulty of minimization, we instead demonstrate how one can build such a formula *incrementally*. Our variational formula will use the dimensions P, Q, R to represent the respective variants. Unique portions of each variant will be nested into the left alternative so that the unique portion is considered when the dimension is bound to true in the configuration.

section on encoding
problem

We begin by combining p and r since the differences² between the two are smaller than between other pairs of feature models in our example. Feature models may be combined in any order as long as the variants in the resulting formula correspond to their plain counterparts. The only change between p and r is the addition of z and thus we wrap the leaf in a choice with dimension R . This yields the following variational formula.

$$f_{pr} = R\langle z, \top \rangle \leftrightarrow (a \wedge b \wedge c \wedge e)$$

We exploit the fact that \wedge forms a monoid with \top to recover a formula equivalent to p for configurations where R is false.

Next we combine f_{pr} with q to obtain a variational formula that encodes the propo-

¹. We hypothesize that it is equivalent to BDD minimization, which is NP-complete, but the equivalence has not been proved; see [86].

²There are many ways to assess the difference of two formulas. For now the reader may consider it reducible to the Levenshtein distance of two strings [55]. We return to this discussion in ...

sitional formulas p , q , r . There are two sub-trees that must be wrapped in choices. First, we must encode the difference between $b \vee \neg i$ from q and b . Second, we must ensure synchronization and thus use the same dimension to encode the difference between $g \rightarrow c$ and e . Thus the resulting variational formula is:

$$f = R\langle z, \mathbb{T} \rangle \leftrightarrow (a \wedge Q\langle b \vee \neg i, b \rangle \wedge c \wedge Q\langle g \rightarrow c, e \rangle)$$

Now that we have constructed the variational formula we need to ensure that it encodes all variants of interest and nothing else. Notice that only 2 dimensions are used to encode 3 variants, because $|f|_D = 2$ we have are 4 possible variants and thus one extra variant. We can observe this by enumerating the variants and possible configurations:

$p = \mathbb{T} \leftrightarrow (a \wedge b \wedge c \wedge e)$	$C = \{(R, \text{false}), (Q, \text{false})\}$
$q = \mathbb{T} \leftrightarrow (a \wedge (b \vee \neg i) \wedge c \wedge (g \rightarrow c))$	$C = \{(R, \text{false}), (Q, \text{true})\}$
$r = z \leftrightarrow (a \wedge b \wedge c \wedge e)$	$C = \{(R, \text{true}), (Q, \text{false})\}$
$extra = z \leftrightarrow (a \wedge (b \vee \neg i) \wedge c \wedge (g \rightarrow c))$	$C = \{(R, \text{true}), (Q, \text{true})\}$

Notice the *extra* variant and that p and q are only recovered through equivalency laws from propositional logic. While it is undesirable that there exists extra variants, the important constraint: $\{p, q, r\} \subseteq \text{Variants}(f)$ is satisfied. We'll return to the case of extra variants in the next chapter as a variational SAT solver must only solve variants end-users are interested in.

maybe superfluous?

Chapter 4: Variational Satisfiability Solving

This chapter presents the variational satisfiability solving algorithm. [Section 4.1](#) provides an overview of the algorithm and introduces the notion of *variational models* as solutions to variational satisfiability problems. [Section 4.5](#) provides the formal specification. We conclude the chapter by proving that the variational solving algorithm is confluent and variation preservation.

add proofs for con-
fluence and variation
preservation

4.1 General Approach

VPL formulas are solved recursively; decoupling the handling of plain terms from the handling of variational terms. The intuition behind the algorithm is to first process as many plain terms as possible (e.g. by pushing those terms to the underlying solver) while skipping choices, yielding a *variational core* that represents only the variational parts of the original formula. We then alternate between configuring choices in the variational core and processing the new plain terms produced by configuration until the entire term has been consumed. A variant in of the original VPL formula is found every time the entire term is consumed, since all choices will have been configured. Once a variant has been found the algorithm queries the underlying solver to obtain

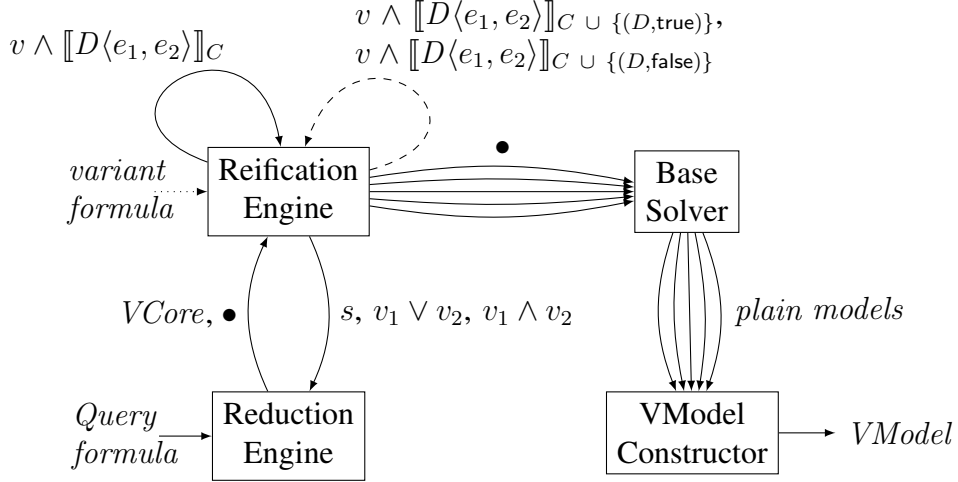

Figure 4.1: System overview of the variational solver.

a model, then backtracks to solve a different variant by configuring the same choices differently. The models for each variant are combined into a single *variational model* that captures the result of solving all variants of the original VPL formula. Crucially building a variational model is associative, and thus the order the variants' models are found is not important to the correctness of the final model.

We present an overview of the variational solver as a state diagram in Fig. 4.1 that operates on the input's abstract syntax tree. Labels on incoming edges denote inputs to a state and labels on outgoing edges denote return values; we show only inputs for recursive edges; labels separated by a comma share the edge. We omit labels that can be derived from the logical properties of connectives, such as commutativity of \vee and \wedge . Similarly, we omit base case edge labels for choices and describe these cases in the text.

The solver has four subsystems: The *reduction engine* processes plain terms and

generates the variational core, which is ready for reification. The *reification engine* configures choices in a variational core. The *base solver* is the incremental solver used to produce plain models. Finally, the *variational model constructor* synthesizes a single variational model from the set of plain models returned by the base solver.

The solver takes a VPL formula called a *query formula* and an optional input called a *variation context* (*vc*). A *vc* is a propositional formula of dimensions that restricts the solver to a subset of variants, thus prevents computation on extra variants. The variational solver translates the query formula to a formula in an intermediate language (IL) that the reduction and reification engines operate over. The syntax of the IL is given below.

$$v ::= \bullet \mid t \mid r \mid s \mid \neg v \mid (v \wedge v) \mid v \vee v \mid D\langle e, e \rangle$$

The IL includes two kinds of terminals not present in the input query formulas: plain subterms that can be reduced symbolically will be replaced by a reference to a *symbolic value* *s*, and subterms that have been sent to the base solver will be represented by the unit value \bullet . Note that choices contain unprocessed expressions (*e*) as alternatives.

4.2 Derivation of a Variational Core

A variational core is an IL formula that captures the variational structure of a query formula. Plain terms will either be placed on the assertion stack or will be symbolically reduced, leaving only logical connectives, symbolic references, and choices.

The variational core for a VPL formula is computed by a reduction engine illustrated in [Fig. 4.2](#). The reduction engine has two states: *evaluation*, which communicates to the

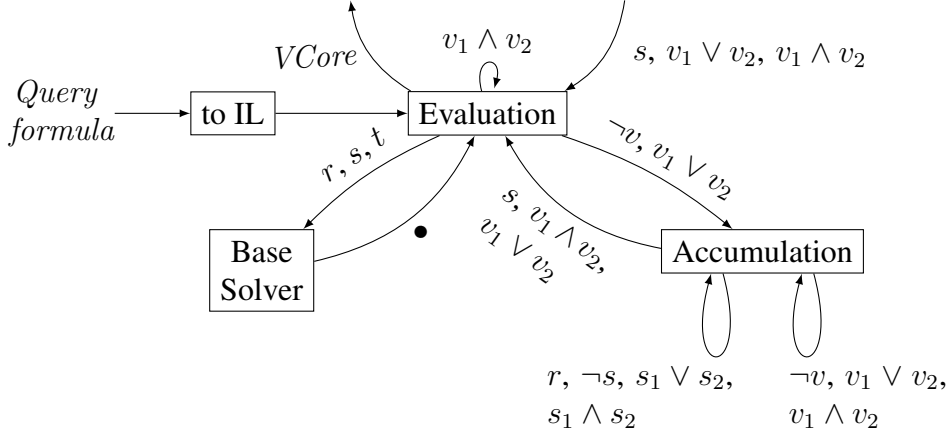

Figure 4.2: Overview of the reduction engine.

base solver to process plain terms, and *accumulation*, which is called by evaluation to create symbolic references and reduce plain formulas.

To illustrate how the reduction engine computes a variational core, consider the query formula $f = ((a \wedge b) \wedge A\langle e_1, e_2 \rangle) \wedge ((p \wedge \neg q) \vee B\langle e_3, e_4 \rangle)$. Translated to an IL formula, f has four references (a, b, p, q) and two choices. The reduction engine will ultimately produce a variational core that asserts $(a \wedge b)$ in the base solver, thus pushing it onto the assertion stack, and create a symbolic reference for $(p \wedge \neg q)$.

Generating the core begins with evaluation. Evaluation matches on the root \wedge node of f and recurs following the $v_1 \wedge v_2$ edge, where $v_1 = (a \wedge b) \wedge A\langle e_1, e_2 \rangle$ and $v_2 = (p \wedge \neg q) \vee B\langle e_3, e_4 \rangle$. The recursion processes the left child first. Thus, evaluation again matches on \wedge of v_1 creating another recursive call with $v'_1 = (a \wedge b)$ and $v'_2 = A\langle e_1, e_2 \rangle$. Finally, the base case is reached with a final recursive call where $v''_1 = a$, and $v''_2 = b$. At the base case, both a and b are references, so evaluation sends a to the base solver

following the r, s, t edge, which returns \bullet for the left child. The right child follows the same process yielding $\bullet \wedge \bullet$. Since the assertion stack implicitly conjuncts all assertions, $\bullet \wedge \bullet$ will be further reduced to \bullet and returned as the result of v'_1 , indicating that both children have been pushed to the base solver. This leaves $v'_1 = \bullet$ and $v'_2 = A\langle e_1, e_2 \rangle$. v'_2 is a base case for choices and cannot be reduced in evaluation, so $\bullet \wedge A\langle e_1, e_2 \rangle$ will be reduced to just $A\langle e_1, e_2 \rangle$ as the result for v_1 .

In evaluation, conjunctions can be split because of the behavior of the assertion stack and the and-elimination property of \wedge . Disjunctions and negations cannot be split in this way because both cannot be performed if a child node has been lost to the solver, e.g., $\neg \bullet$. Thus, in accumulation, we construct symbolic terms to represent entire subtrees, which ensures information is not lost while still allowing for the subtree to be evaluated if it is sound to do so.

The right child, $v_2 = (p \wedge \neg q) \vee B\langle e_3, e_4 \rangle$ requires accumulation. Evaluation will match on the root \vee and send $(p \wedge \neg q) \vee B\langle e_3, e_4 \rangle$ to accumulation via the $v_1 \vee v_2$ edge. Accumulation has two self-loops, one to create symbolic references (with labels r, s, \dots), and one to recur to values. Accumulation matches the root \vee and recurs on the self-loop with edge $v_1 \vee v_2$, where $v_1 = (p \wedge \neg q)$ and $v_2 = B\langle e_3, e_4 \rangle$. Processing the left child first, accumulation will recur again with $v'_1 = p$ and $v'_2 = \neg q$. $v'_1 = p$ is a base case for references, so a unique symbolic reference s_p is generated for p following the self-loop with label r and returned as the result for v'_1 . v'_2 will follow the self-loop with label $\neg v$ to recur through \neg to q , where a symbolic term s_q will be generated and returned. This yields $\neg s_q$, which follows the $\neg s$ edge to be processed into a new symbolic term, yielding the result for v'_2 as $s_{\neg q}$. With both results $v_1 = s_p \wedge s_{\neg q}$, accumulation will match

on \wedge and both s_p and $s_{\neg q}$ to accumulate the entire subtree to a single symbolic term, s_{pq} , which will be returned as the result for v_1 . v_2 is a base case, so accumulation will return $s_{pq} \vee B\langle e_3, e_4 \rangle$ to evaluation. Evaluation will conclude with $A\langle e_1, e_2 \rangle$ as the result for the left child of \wedge and $s_{pq} \vee B\langle e_3, e_4 \rangle$ for the right child, yielding $A\langle e_1, e_2 \rangle \wedge s_{pq} \vee B\langle e_3, e_4 \rangle$ as the variational core of f .

A variational core is derived to save redundant work. If solved naively, plain sub-formulas of f , such as $a \wedge b$ and $p \wedge \neg q$, would be processed once for each variant even though they are unchanged. Evaluation moves sub-formulas into the solver state to be reused among different variants. Accumulation caches sub-formulas that cannot be immediately evaluated to be evaluated later.

Symbolic references are variables in the reduction engine's memory that represent a set of statements in the base solver.¹ For example, s_{pq} represents three declarations in the base solver:

```
(declare-const p Bool)
(declare-const q Bool)
(declare-fun spq () Bool (and p (not q)))
```

Similarly a variational core is a sequence of statements in the base solver with holes

◇. For example, the variational core of f would be encoded as:

```
(assert (and a b))           ;; add  $a \wedge b$  to the assertion stack
(declare-const ◇)           ;; choice A
:                           ;; potentially many declarations and assertions
(declare-fun spq () Bool (and p q)) ;; get symbolic reference for  $s_{pq}$ 
(declare-const ◇)           ;; choice B
:                           ;; potentially many declarations and assertions
(assert (or sab ◇))         ;; assert waiting on  $\llbracket B\langle e_3, e_4 \rangle \rrbracket_C$ 
```

¹Note that while we use SMTLIB2 as an implementation target, any solver that exposes an incremental API as defined by minisat [65] can be used to implement variational satisfiability solving.

Each hole is filled by configuring a choice and may require multiple statements to process the alternative.

4.3 Solving the Variational Core

The reduction engine performs the work at each recursive step whereas the reification engine defines transitions between the recursive steps by manipulating the configuration. In [Chapter 3](#), we formalized a configuration as a function $D \rightarrow \mathbb{B}$, which we encode in the solver as a set of tuples $\{D \times \mathbb{B}\}$. [Fig. 4.1](#) shows two loops for the reification engine corresponding to the reification of choices. The edges from the reification engine to the reduction engine are transitions taken after a choice is removed, where new plain terms have been introduced and thus a new core is derived. If the user supplied a variation context, then it is used to check that the binding of a Boolean value to a dimension is valid in the variation context. For example, $vc = \neg A$ would prevent any configurations where $(A, \text{true}) \in C$. Finally, a model is retrieved from the base solver when the reduction engine returns \bullet , indicating that a variant has been reached.

We show the edges of the reification engine relating to the \wedge connective; the edges for the \vee connective are similar. The left edge is taken when a choice is observed in the variational core: $v \wedge \llbracket D \langle e_1, e_2 \rangle \rrbracket_C$ and $D \in C$. This edge reduces choices with dimension D to an alternative, which is then translated to IL. The right edge is dashed to indicate assertion stack manipulation and is taken when $D \notin C$. For this edge, the configuration is mutated for both alternatives: $C \cup \{(D, \text{true})\}$ and $C \cup \{(D, \text{false})\}$, and the recursive call is wrapped with a PUSH and POP command. To the base solver, this

branching appears as a linear sequence of assertion stack manipulations that performs backtracking behavior. For example, the representation of f is:

```

:           ;; declarations and assertions from variational core
(push 1)    ;; a configuration on B has occurred
:           ;; new declarations for left alternative
(declare-fun s () Bool (or spq  $\Diamond[\Diamond \rightarrow s_{B_T}]$ )) ;; fill
(assert s)
:           ;; recursive processing
(pop 1)     ;; return for the right alternative
(push 1)    ;; repeat for right alternative

```

Where the hole \Diamond , will be filled with a newly defined variable s_{D_T} that represents the left alternative's formula.

4.4 Variational Models

Classic SAT models map variables to Boolean values; variational models map variables to variation contexts that record the variants where the variable was assigned \top . The variational context for a variable r is denoted as vc_r , and a variational model reserves a special variable called $_Sat$ to track the configurations that were found satisfiable.

As an example, consider an altered version of the query formula from the previous

$a \rightarrow \top$	$a \rightarrow \top$	$a \rightarrow \top$
$b \rightarrow \text{F}$	$b \rightarrow \text{F}$	$b \rightarrow \text{F}$
$c \rightarrow \top$	$c \rightarrow \top$	
$p \rightarrow \top$	$p \rightarrow \top$	$p \rightarrow \text{F}$
$q \rightarrow \text{F}$	$q \rightarrow \text{F}$	$q \rightarrow \top$
$C_{FF} = \{(A, \text{F}), (B, \text{F})\}$	$C_{FT} = \{(A, \text{F}), (B, \top)\}$	$C_{TT} = \{(A, \top), (B, \top)\}$

Figure 4.3: Possible plain models for variants of f .

$$\begin{aligned}
_Sat &\rightarrow (\neg A \wedge \neg B) \vee (\neg A \wedge B) \vee (A \wedge B) \\
a &\rightarrow (\neg A \wedge \neg B) \vee (\neg A \wedge B) \vee (A \wedge B) \\
b &\rightarrow \text{F} \\
c &\rightarrow (\neg A \wedge \neg B) \vee (\neg A \wedge B) \\
p &\rightarrow (\neg A \wedge \neg B) \vee (\neg A \wedge B) \\
q &\rightarrow (A \wedge B)
\end{aligned}$$

Figure 4.4: Variational model corresponding to the plain models in Fig. 4.3.

section $f = ((a \wedge \neg b) \wedge A \langle a \rightarrow \neg p, c \rangle) \wedge ((p \wedge \neg q) \vee B \langle q, p \rangle)$. We can easily see that one variant, with configuration $\{(A, \text{T}), (B, \text{F})\}$ is unsatisfiable. If the remaining variants are satisfiable, then three models would result, as illustrated in Fig. 4.3; with the corresponding variational model shown in Fig. 4.4.

We see that vc_Sat consists of three disjuncted terms, one for each satisfiable variant. Variational models are flexible; a satisfiable assignment of the query formula can be found by calling SAT on vc_Sat . Assuming the model $C_{FT} = \{(A, \text{F}), (B, \text{T})\}$ is returned, one can find a variable's value through substitution with the configuration; for example, substituting the returned model on vc_c yields:

$$\begin{array}{ll}
c \rightarrow (\neg A \wedge \neg B) \vee (\neg A \wedge B) & vc \text{ for } c \\
c \rightarrow (\neg \text{F} \wedge \neg \text{T}) \vee (\neg \text{F} \wedge \text{T}) & \text{Substitute F for A, T for B} \\
c \rightarrow \text{T} & \text{Result}
\end{array}$$

Furthermore, finding variants where a variable such as c is satisfiable is reduced to $SAT(vc_c)$

Variational models are constructed incrementally by merging each new plain model

returned by the solver into the variational model. A merge requires the current configuration, the plain model, and current vc of a variable. Variables are initialized to \mathbb{F} . For each variable i in the model, if i 's assignment is \mathbb{T} in the plain model, then the configuration is translated to a variation context and disjuncted with vc_i . For example, to merge the C_{FT} 's plain model to the variational model in Fig. 4.4, C_{FT} 's configuration is converted to $\neg A \wedge B$. This clause is disjuncted for variables assigned \mathbb{T} in the plain model: vc_a , vc_c , and vc_p , even if they are new (e.g., c). Variables assigned \mathbb{F} are skipped, thus vc_q remains \mathbb{F} . For example, in the next model C_{TT} , c is \mathbb{F} thus vc_c remains unaltered, while vc_q flips to \mathbb{T} hence vc_q records $A \wedge B$. Variables such as b , whose vc 's stay \mathbb{F} are called *constant*.

Variational models are constructed in disjunctive normal form (DNF), and form a monoid with \vee as the semigroup operation, and \mathbb{F} as the unit value. We note this for mathematically inclined readers and those looking to implement their own variational solver because it has important ramifications for the asynchronous version of variational satisfiability solvers.

4.5 Formalization

In this section we formalize variational SAT solving by specifying the semantics of the *accumulation* and *evaluation* phases of the variational solver, as well as the semantics of processing the variational core, which we call *choice removal*. Variational SAT solving assumes the existence of an underlying incremental SAT solver, which we refer to as the *base solver*.

Not	: $(\Delta, s) \rightarrow (\Delta, s)$	<i>Negate a symbolic value</i>
And	: $(\Delta, s, s) \rightarrow (\Delta, s)$	<i>Conjunction of symbolic values</i>
Or	: $(\Delta, s, s) \rightarrow (\Delta, s)$	<i>Disjunction of symbolic values</i>
Var	: $(\Delta, r) \rightarrow (\Delta, s)$	<i>Create symbolic value based on a variable</i>
Assert	: $(\Gamma, \Delta, s) \rightarrow \Gamma$	<i>Assert a symbolic value to the solver</i>
GetModel	: $(\Gamma, \Delta) \rightarrow m$	<i>Get a model for the current solver state</i>

Figure 4.5: Assumed base solver primitive operations.

The variational solver interacts with the base solver via several primitive operations. In our semantics, we simulate the effects of these primitive operations by tracking their effects on two stores. The *accumulation store* Δ tracks values cached during accumulation by mapping IL terms to symbolic references. The *evaluation store* Γ tracks the symbolic references that have been sent to the base solver during evaluation.

4.5.1 Primitives

Fig. 4.5 lists a minimal set of primitive operations that the base solver is assumed to support. These primitive operations define the interface between the base solver and the variational solver.

The primitive operations can be roughly grouped into two categories: The first four operations, consisting of the logical operations Not, And, and Or, plus the Var operation, are used in the accumulation phase and are concerned with creating and maintaining symbolic references that may stand for arbitrarily complex subtrees of the original formula. These operations simulate caching information in the base solver. The final two operations, Assert and GetModel, are used in the evaluation phase and simulate pushing new assertions to the base solver and obtaining a satisfiability model based

on the current solver state, respectively.

It's important to note that our primitive operations are pure functions and do not simulate interacting with the base solver via side effects. The effect of a primitive operation can be determined by observing its type. For example, the `Assert` operation pushes new assertions to the base solver. This is reflected in its type, which includes an evaluation store as input and produces a new evaluation store (with the assertion included) as output. Since evaluation stores are immutable, we do not need a primitive operation to simulate popping assertions from the base solver. Instead, we simulate this by directly reusing old evaluation stores.

Many of the primitive operations operate on references to symbolic values. Such symbolic references may stand for arbitrarily complex subtrees of the original formula, built up through successive calls to the corresponding primitive operations. For example, recall the example formula $p \wedge \neg q$ from [Section 4.1](#), which was replaced by the symbolic value s_{pq} after the following sequence of `smtlib` declarations.

```
(declare-const p Bool)
(declare-const q Bool)
(declare-fun spq () Bool (and p (not q)))
```

In our formalization, we would represent this same transformation of the formula $p \wedge \neg q$ into a symbolic reference s_{pq} using the following sequence of primitive operations:

$$\begin{aligned}
 \text{Var}(\Delta_0, p) &= (\Delta_1, s_p) \\
 \text{Var}(\Delta_1, q) &= (\Delta_2, s_q) \\
 \text{Not}(\Delta_2, s_q) &= (\Delta_3, s'_q) \\
 \text{And}(\Delta_3, s_p, s'_q) &= (\Delta_4, s_{pq})
 \end{aligned}$$

The accumulation store tracks what information is associated with each symbolic reference. The store must therefore be threaded through the calls to each primitive operation so that subsequent operations have access to existing definitions and can produce a new, updated store. For example, the final store produced by the above example contains the following mappings from IL terms to symbolic references, $\Delta_4 = \{(p, s_p), (q, s_q), (\neg s_q, s'_q), (s_p \wedge s'_q, s_{pq})\}$.

When comparing the `smtlib` notation to our formalization, observe that each use of `declare-const` corresponds to a use of the `Var` primitive, while the `declare-fun` line in `smtlib` may potentially expand into several primitive operations in our formalization. For the evaluation primitives, the `Assert` operation corresponds to an `smtlib assert` call, while the `GetModel` operation corresponds roughly to an `smtlib check-sat` call, which retrieves a model for the current set of assertions on the stack. However, the exact semantics of `check-sat` depends on the base solver in use. For example, given the plain formula $p = a \vee b \vee c$, `z3` returns only a minimal satisfiable model, such as $\{b = \text{T}\}$, providing no values for the other variables in the formula. To normalize this behavior across solvers, we instead consider `GetModel` equivalent to `check-sat` followed by a `get-value` call for every variable in the query formula, yielding a complete model. For example, a complete model for p would be $\{a = \text{F}, b = \text{T}, c = \text{F}\}$.

Finally, in [Fig. 4.6](#) we define wrapped versions of the primitive operations used in accumulation. These wrapper functions first check to see whether a symbolic reference for the given IL term exists already in the accumulation store, and if so, returns it without changing the store. Otherwise, it invokes the corresponding primitive operation to generate and return the new symbolic reference and updated store.

$$\begin{aligned}
\underline{\text{Var}}(\Delta, r) &= \begin{cases} (\Delta, s) & (r, s) \in \Delta \\ \text{var}(\Delta, r) & \text{otherwise} \end{cases} \\
\underline{\text{Not}}(\Delta, s) &= \begin{cases} (\Delta, s') & (\neg s, s') \in \Delta \\ \text{Not}(\Delta, s) & \text{otherwise} \end{cases} \\
\underline{\text{And}}(\Delta, s_1, s_2) &= \begin{cases} (\Delta, s_3) & (s_1 \wedge s_2, s_3) \in \Delta \\ \text{And}(\Delta, s_1, s_2) & \text{otherwise} \end{cases} \\
\underline{\text{Or}}(\Delta, s_1, s_2) &= \begin{cases} (\Delta, s_3) & (s_1 \vee s_2, s_3) \in \Delta \\ \text{Or}(\Delta, s_1, s_2) & \text{otherwise} \end{cases}
\end{aligned}$$

Figure 4.6: Wrapped accumulation primitive operations.

4.5.2 Accumulation

The accumulation phase is formally specified in [Fig. 4.7](#) as a relation of the form $(\Delta, v) \mapsto (\Delta', v')$. Accumulation replaces plain subterms of the formula with references to symbolic values, wherever possible. The replacement of subterms by symbolic references is achieved by the first four rules in the figure. In the A-REF rule, a variable reference is replaced by a symbolic reference by invoking the wrapped version of the `Var` primitive, which returns the corresponding symbolic reference or generates a new one, if needed. The A-NOT-S, A-AND-S, and A-OR-S rules all similarly replace an IL term by a symbolic reference by invoking the corresponding wrapped primitive operation. These rules all require that their subterms completely reduce to symbolic references, as illustrated by the premise $(\Delta, v) \mapsto (\Delta', s)$ in the A-NOT-S rule, otherwise the primitive operation cannot be invoked.

However, not all subterms can be completely reduced to symbolic references. In par-

$$\begin{array}{c}
\frac{\text{Var}(\Delta, r) = (\Delta', s)}{(\Delta, r) \mapsto (\Delta', s)} \text{ A-REF} \\
\\
\frac{(\Delta, v) \mapsto (\Delta', s) \quad \text{Not}(\Delta', s) = (\Delta'', s')}{(\Delta, \neg v) \mapsto (\Delta'', s')} \text{ A-NOT-S} \\
\\
\frac{(\Delta, v_1) \mapsto (\Delta_1, s_1) \quad (\Delta_1, v_2) \mapsto (\Delta_2, s_2) \quad \text{And}(\Delta_2, s_1, s_2) = (\Delta_3, s_3)}{(\Delta, v_1 \wedge v_2) \mapsto (\Delta_3, s_3)} \text{ A-AND-S} \\
\\
\frac{(\Delta, v_1) \mapsto (\Delta_1, s_1) \quad (\Delta_1, v_2) \mapsto (\Delta_2, s_2) \quad \text{Or}(\Delta_2, s_1, s_2) = (\Delta_3, s_3)}{(\Delta, v_1 \vee v_2) \mapsto (\Delta_3, s_3)} \text{ A-OR-S} \\
\\
\frac{}{(\Delta, D\langle e_1, e_2 \rangle) \mapsto (\Delta, D\langle e_1, e_2 \rangle)} \text{ A-CHC} \quad \frac{(\Delta, v) \mapsto (\Delta', v')}{(\Delta, \neg v) \mapsto (\Delta', \neg v')} \text{ A-NOT-V} \\
\\
\frac{(\Delta, v_1) \mapsto (\Delta_1, v'_1) \quad (\Delta_1, v_2) \mapsto (\Delta_2, v'_2)}{(\Delta, v_1 \wedge v_2) \mapsto (\Delta_2, v'_1 \wedge v'_2)} \text{ A-AND-V} \\
\\
\frac{(\Delta, v_1) \mapsto (\Delta_1, v'_1) \quad (\Delta_1, v_2) \mapsto (\Delta_2, v'_2)}{(\Delta, v_1 \vee v_2) \mapsto (\Delta_2, v'_1 \vee v'_2)} \text{ A-OR-V}
\end{array}$$

Figure 4.7: Accumulation inference rules.

ticular, variational subterms—subterms that contain one or more choices within them—cannot be accumulated to a symbolic reference. The A-CHC rule prevents accumulation under a choice. The A-NOT-V, A-AND-V, and A-OR-V rules are congruence rules that recursively apply accumulation to subterms. Although not explicitly stated in the premises, it is assumed that these A-* -V rules apply only if the corresponding A-* -S rule does not apply, that is, when at least one of the subterms does not reduce completely to a symbolic reference.

We have omitted rules for processing the constant values T and F . These rules correspond closely to the A-REF rule, but use a predefined variable reference for the true and false constants.

To illustrate the semantics of accumulation, consider the plain formula $g = a \vee (a \wedge b)$ with an initial accumulation store $\Delta = \emptyset$. The A-OR-S rule matches the root \vee connective with $v_1 = a$ and $v_2 = a \wedge b$. Since v_1 is a reference, the A-REF rule applies, generating a new symbolic reference s_a and returning the store $\Delta_1 = \{(a, s_a)\}$. Processing v_2 requires an application of the A-AND-S rule with $v'_1 = a$ and $v'_2 = b$, both of which require another application of the A-REF rule. For v'_1 , the variable a is found in the store returning s_a , while for v'_2 , a new symbolic reference s_b is generated and added to the resulting store $\Delta_2 = \{(a, s_a), (b, s_b)\}$. Since both the left and right sides of v_2 reduce to a symbolic reference, the And primitive is invoked, yielding a new symbolic reference s_{ab} and the store $\Delta_3 = \{(a, s_a), (b, s_b), (a \wedge b, s_{ab})\}$. Finally, since both the left and right sides of the original formula g reduce to symbolic references, the Or primitive is invoked yielding the final symbolic reference s_g and the final accumulation store $\Delta_4 = \{(a, s_a), (b, s_b), (s_a \wedge s_b, s_{ab})(s_a \vee s_{ab}, s_g)\}$.

$$\begin{array}{c}
\frac{(\Delta, v) \mapsto (\Delta', v') \quad (\Gamma, \Delta', v') \multimap (\Gamma', \Delta'', v'')}{(\Gamma, \Delta, v) \multimap (\Gamma', \Delta'', v'')} \text{E-ACC} \quad \frac{\text{Assert}(\Gamma, \Delta, s) = \Gamma'}{(\Gamma, \Delta, s) \multimap (\Gamma', \Delta, \bullet)} \text{E-SYM} \\
\\
\frac{}{(\Gamma, \Delta, D\langle e_1, e_2 \rangle) \multimap (\Gamma, \Delta, D\langle e_1, e_2 \rangle)} \text{E-CHC} \quad \frac{}{(\Gamma, \Delta, v_1 \vee v_2) \multimap (\Gamma, \Delta, v_1 \vee v_2)} \text{E-OR} \\
\\
\frac{(\Gamma, \Delta, v_1) \multimap (\Gamma_1, \Delta_1, \bullet) \quad (\Gamma_1, \Delta_1, v_2) \multimap (\Gamma_2, \Delta_2, v'_2)}{(\Gamma, \Delta, v_1 \wedge v_2) \multimap (\Gamma_2, \Delta_2, v'_2)} \text{E-AND-L} \\
\\
\frac{(\Gamma, \Delta, v_1) \multimap (\Gamma_1, \Delta_1, v'_1) \quad (\Gamma_1, \Delta_1, v_2) \multimap (\Gamma_2, \Delta_2, \bullet)}{(\Gamma, \Delta, v_1 \wedge v_2) \multimap (\Gamma_2, \Delta_2, v'_1)} \text{E-AND-R} \\
\\
\frac{(\Gamma, \Delta, v_1) \multimap (\Gamma_1, \Delta_1, v'_1) \quad (\Gamma_1, \Delta_1, v_2) \multimap (\Gamma_2, \Delta_2, v'_2)}{(\Gamma, \Delta, v_1 \wedge v_2) \multimap (\Gamma_2, \Delta_2, v'_1 \wedge v'_2)} \text{E-AND}
\end{array}$$

Figure 4.8: Evaluation inference rules.

When a formula contains choices, all of the plain subterms surrounding the choices are accumulated to symbolic references, but choices remain in place and their alternatives are not accumulated. For example, consider the variational formula $g' = (a \vee (a \wedge b)) \vee D\langle a, a \wedge b \rangle \wedge (a \vee (a \wedge b))$ which contains two instances of g as subterms. The formula g' accumulates to the variational core $s_g \vee D\langle a, a \wedge b \rangle \wedge s_g$ with the same final store Δ_4 produced when accumulating g alone. Note that the each instance of g in g' was reduced to the same symbolic reference s_g and the alternatives of the choice were not reduced.

4.5.3 Evaluation

The evaluation phase is formally specified in Fig. 4.8 as a relation of the form $(\Gamma, \Delta, v) \mapsto (\Gamma', \Delta', v')$, where an evaluation store Γ represents the base solver's state. The E-ACC and E-SYM rules are the heart of evaluation: the E-ACC rule enables accumulating subterms during evaluation, while the E-SYM rule sends a fully accumulated subterm to the base solver. Evaluation cannot occur under choices or un-accumulated disjunctions (i.e. disjunctions that contain choices), as seen in the E-CHC and E-OR rules, but can occur under un-accumulated conjunctions, as reflected by the three E-AND* rules. This will be explained in more detail below.

When a subterm is sent to the base solver by E-SYM, it is replaced by the unit value \bullet and the evaluation store Γ is updated accordingly. Conceptually, the evaluation store represents the internal state of the underlying solver (e.g. z3's internal state), but we model it formally as the set of assertions that have been sent to the solver. For example, given the accumulation store $\Delta = \{(a, s_a), (b, s_b), (s_a \wedge s_b, s_{ab})\}$, the assertion $\text{Assert}(\{\}, \Delta, s_a)$ yields $\{s_a\}$ and subsequent assertions add more elements to this set, for example, $\text{Assert}(\{s_a\}, \Delta, s_{ab}) = \{s_a, s_{ab}\}$. The assertions sent to a SAT solver are implicitly conjuncted together, which is why partially accumulated conjunctions may still be evaluated, but partially accumulated disjunctions may not. Such disjunctions are instead handled during choice removal using back-tracking.

The three E-AND* rules propagate accumulation over conjunctions. In all three rules, the subterms are evaluated left-to-right, propagating the resulting stores accordingly. The E-AND-L rule states that if the left side of a conjunction can be fully evaluated to \bullet ,

then the expression can be evaluated to the result of the right side; likewise, E-AND-R states that if the right side fully evaluates, the result of evaluating the expression is the result of the left side. If neither side fully evaluates to \bullet (i.e. because both contain choices or disjunctions), then E-AND applies, which leaves the conjunction in place (with evaluated subterms) to be handled during choice removal.

Consider evaluating the formula $g = (a \vee b) \wedge D\langle a, c \rangle$ with initially empty stores. We start by applying accumulation using the E-ACC rule, yielding the intermediate term $g' = s_{ab} \wedge D\langle a, c \rangle$ with the accumulation store $\Delta = \{(a, s_a), (b, s_b), (s_a \vee s_b, s_{ab})\}$. We then apply E-AND-L to g' , which sends the left subterm s_{ab} to the base solver via the E-SYM rule, and the right side will be unevaluated via the E-CHC rule. Ultimately, evaluation yields the expression $D\langle a, c \rangle$ with accumulation store Δ and evaluation store $\{s_{ab}\}$.

4.5.4 Choice removal

The main driver of variational solving is the choice removal phase, which is formally specified in Fig. 4.9 as a relation of the form $(C, \Gamma, \Delta, M, z, v) \Downarrow M'$. The main role of choice removal is to relate an IL term v to a variational model M' . However, to do this requires several pieces of context including a configuration C , an evaluation store Γ , an accumulation store Δ , an initial variational model M , and an evaluation context z . The two stores have been explained earlier in this chapter, and variational models are explained at the end of Section 4.1. We explain configurations and evaluation contexts

in the context of the relevant rules below.

are the C-AND like rules wrong? Should the v_1 be in the focus not v_2

$$\begin{array}{c}

\\
\frac{(\Delta, s_1 \vee s_2) \mapsto (\Delta', s_3) \quad (C, \Gamma, \Delta, M, z, s_3) \Downarrow M'}{(C, \Gamma, \Delta, M, s_1 \vee \cdot :: z, s_2) \Downarrow M'} \text{C-OR-INR}
\end{array}$$

Figure 4.9: Choice removal inference rules

The C-EVAL rule states that v fully evaluates to \bullet , then we can get the current model from the base solver using the `GetModel` primitive and update our variational model. We use the operation `Combine` to perform the variational model update operation described in [Section 4.1](#). The rest of the choice removal rules are structured so that C-EVAL will be invoked once for every variant of the variational core so that the final output will be a variational model that encodes the solutions to every variant of the original formula.

is there a missing rule to convert references to symbolic with accumulation?

The next three rules concern choices and are the heart of choice removal. These rules make use of a *configuration* C , which maps dimensions to Boolean values (encoded as a set of pairs). The configuration tracks which dimensions have been selected and how to ensure that all choices in the same dimension are synchronized. Whenever a choice $D\langle e_1, e_2 \rangle$ is encountered during choice removal, we check C to determine what to do. In C-CHC-T, if $(D, \text{true}) \in C$, then the first alternative of the dimension has already been selected, so choice removal proceeds on e_1 . Similarly, in C-CHC-F, if $(D, \text{false}) \in C$, the right alternative has been selected, so choice removal proceeds on e_2 . In C-CHC, if $D \notin \text{dom}(C)$, then the dimension has not yet been selected, so we recursively apply choice removal to both e_1 and e_2 , updating C accordingly in each case. Observe that we use the same accumulation store, evaluation store, and evaluation context for each alternative. This simulates a backtracking point in the solver, where we first solve e_1 , then reset the state of the solver to the point where we encountered the choice and solve e_2 . Only the variational model, which is threaded through the solution of both e_1 and e_2 , is maintained to accumulate the results of solving each alternative.

The final eight rules apply choice removal to the logical operations. These rules make heavy use of an *evaluation context* z that keeps track of where we are in a partially

evaluated IL term during choice removal. Evaluation contexts are defined as a zipper data structure [49] over IL terms, given by the following grammar.

$$z ::= \top \mid \neg \cdot :: z \mid \cdot \wedge v :: z \mid s \wedge \cdot :: z \mid \cdot \vee v :: z \mid s \vee \cdot :: z$$

An evaluation context z is like a breadcrumb trail that enables focusing on a subterm within a partially evaluated IL term while also keeping track of work left to do. The empty context \top indicates the root of the term. The other cases in the grammar prepend a “crumb” to the trail. The crumb $\cdot \neg$ focuses on the subterm within a negation, $\cdot \wedge v$ focuses on the left subterm within a conjunction whose right subterm is v , and $v \wedge \cdot$ focuses on the right subterm of a conjunction whose left subterm has already been reduced to s . The cases for disjunction are similar to conjunction.

As an example, consider the IL term $\neg(a \vee b) \wedge c$. When evaluation is focused on a , the evaluation context will be $\cdot \vee b :: \neg \cdot :: \cdot \wedge c :: \top$, which states that a exists as the left child of a disjunction whose right child is b , which is inside a negation, which is the left child of a conjunction whose right child is c . The b and c terms captured in the context are subterms of the original term that must still be evaluated. During choice removal, IL terms are evaluated according to a left-to-right, post-order traversal; as IL subterms are evaluated they are replaced by symbolic references via accumulation. When evaluation is focused on b , the context will be $s_a \vee \cdot :: \neg \cdot :: \cdot \wedge c :: \top$, where s_a is the symbolic reference produced by accumulating the variable a . When evaluation is eventually focused on c , the evaluation context will be simply $s_{ab} \wedge \cdot :: \top$ since the entire subtree $\neg(a \vee b)$ on the left side of the conjunction will have been accumulated to

the symbolic reference s_{ab} .

The C-NOT, C-AND, and C-OR rules define what to do when encountering a logical operation for the first time. In C-NOT, we focus on the subterm of the negation, while in C-AND and C-OR, we focus on the left child while saving the right child in the context. The C-AND-INL and C-OR-INL rules define what to do when *finished* processing the left child of the corresponding operation. A fully processed child have been accumulated to a symbolic reference s . At this point, we move the s into the evaluation context and shift focus to the previously saved right child of the logical operation. Finally, the C-NOT-IN, C-AND-INR, and C-OR-INR rules define what to do when finished processing all children of a logical operation. At this point, all children will have been reduced to symbolic references so we can accumulate the entire subterm and apply choice removal to the result. For example, in C-AND-INR, we have just finished processing the right child to s_2 and we previously reduced the left child to s_1 , so we now accumulate $s_1 \vee s_2$ to s_3 and proceed from there.

Evaluation contexts support a simple recursive approach to solving variational formulas by adding to the context as we move down the term and removing from the context as we move back up. The extra effort over a more direct recursive strategy is necessary to support the backtracking pattern implemented by the C-CHC rule. Whenever we encounter a choice in a new dimension, we can simply split the state of the solver to explore each alternative. Without evaluation contexts, this would be extremely difficult since choices may be deeply nested within a variational formula. We would have to somehow remember all of the locations in the term that we must backtrack to later and the state of the solver at each of those locations.

Chapter 5: Variational Satisfiability-Modulo Theory Solving

We have covered the basics of variational satisfiability solving. In this chapter we generalize the variational solving procedure to variational SMT solving. SMT solvers generalize SAT solvers through the use of *background theories* that allow the solver to reason about values and constructs outside the Boolean domain. The SMTLIB2 standard defines seven such background theories: CORE (Boolean theory), ARRAYSEX, FIXEDSIZEBITVECTORS, FLOATINGPOINT, INTS, REALS, and REAL_INTS. In this chapter, we use integer arithmetic (INTS) as an example SMT extension for variational SMT solving. Extensions for other background theories are similar to the INTS extension with the exception of the array theory. The array theory presents unique challenges due to interactions with choices; we conclude the section by presenting the array extension thus recovering the most popular SMT background theories in the variational solver.

5.1 Variational propositional logic extensions and primitives

In order to construct a variational SMT solver we must first extend VPL to include non-Boolean values. VPL included two kinds of relations: relations such as \neg and \vee which required accumulation in the presence of variation, and relations such as \wedge which required no special handling. Unfortunately, in the presence of variation there are no relations such as \wedge for the SMT theories. Thus we add support for each theory

Figure 5.3: Assumed base solver primitive operations for $\text{VPL}^{\mathbb{Z}}$

except arrays through accumulation. Our strategy to extend VPL to $\text{VPL}^{\mathbb{Z}}$ is to add the appropriate cases to the syntax of VPL, extend the intermediate language, add the requisite primitive operations, and then extend the inference rules of accumulation and choice removal.

The $\text{VPL}^{\mathbb{Z}}$ syntax is presented in Fig. 5.1. $\text{VPL}^{\mathbb{Z}}$ includes syntax of the integer arithmetic extension, which consists of integer variables, integer literals, a set of standard operators, and choices. The sets of Boolean and arithmetic variables are disjoint, thus an expression such as $(s < 10) \wedge (s \vee p)$, where s occurs as both an integer and Boolean variable is disallowed. The syntax of the language prevents type errors and expressions that do not yield Boolean values. For example, $D\langle 1, 2 \rangle \wedge p$ is syntactically invalid. Thus, the language is purposefully limited to arithmetic expressions that have an inequality at

$$\begin{aligned}
\underline{\text{Var}_i}(\Delta, r_i) &= \begin{cases} (\Delta, s) & (r_i, s) \in \Delta \\ \text{Var}_i(\Delta, r_i) & \text{otherwise} \end{cases} \\
\underline{\text{Neg}}(\Delta, s) &= \begin{cases} (\Delta, s') & (-s, s') \in \Delta \\ \text{Neg}(\Delta, s) & \text{otherwise} \end{cases} \\
\underline{\text{Add}}(\Delta, s_1, s_2) &= \begin{cases} (\Delta, s_3) & (s_1 + s_2, s_3) \in \Delta \\ \text{Add}(\Delta, s_1, s_2) & \text{otherwise} \end{cases} \\
\underline{\text{Sub}}(\Delta, s_1, s_2) &= \begin{cases} (\Delta, s_3) & (s_1 - s_2, s_3) \in \Delta \\ \text{Sub}(\Delta, s_1, s_2) & \text{otherwise} \end{cases} \\
\underline{\text{Div}}(\Delta, s_1, s_2) &= \begin{cases} (\Delta, s_3) & (s_1 \div s_2, s_3) \in \Delta \\ \text{Div}(\Delta, s_1, s_2) & \text{otherwise} \end{cases} \\
\underline{\text{Mult}}(\Delta, s_1, s_2) &= \begin{cases} (\Delta, s_3) & (s_1 * s_2, s_3) \in \Delta \\ \text{Mult}(\Delta, s_1, s_2) & \text{otherwise} \end{cases}
\end{aligned}$$

Figure 5.5: Syntactic categories of primitive operations

the root of the expression, such as: $g = (A\langle 1, 2 \rangle + j \geq 2) \vee a \wedge A\langle c, d \rangle$. Choices in the same dimension are synchronized across Boolean and arithmetic sub-expressions, for example, the expression $g = (A\langle 1, 2 \rangle + j \geq 2) \vee (a \wedge A\langle c, d \rangle)$ represents two variants: $\llbracket g \rrbracket_{\{(A, \text{true})\}} = (1 + j \geq 2) \vee (a \wedge c)$ and $\llbracket g \rrbracket_{\{(A, \text{false})\}} = (2 + j \geq 2) \vee (a \wedge d)$.

Similarly to [Chapter 4](#), we define the assumed primitive operations of the base solver in [Fig. 5.3](#), and wrapped versions for new operators in [Fig. 5.4a](#) and [Fig. 5.4b](#). The wrapped versions are defined identically as the wrapped primitives in [Fig. 4.6](#) and serve the same purpose. From the perspective of the variational solver, operations such as addition, division, and subtraction only differ in the primitive operation emitted to the base solver. Thus, we define syntactic categories over like operations in [Fig. 5.5](#). Notice that the categories correspond to the respective type of each operation. For exam-

ple, the boolean categories encapsulate operations which take two boolean expressions and return a boolean expression, similarly the inequality category encapsulate operators which take numeric expressions and return boolean expressions. Further SMT extensions would directly copy this pattern, that is, defining a syntactic category of `FIXEDSIZEBITVECTOR` or `REALS` operators. Similarly, while we present only a single arithmetic unary function $-$, other arithmetic unary functions would be straightforward to add. For example, to include a modulus operator *mod*, one would define the wrapped primitive, and add the operator to the appropriate syntactic category without requiring any modification to the inference rules or intermediate languages.

Just as VPL was extended the intermediate language must be extended. First we must add cases for inequality operations, and second we must define an intermediate language for the arithmetic domain. [Fig. 5.6](#) defines the intermediate arithmetic language $ar^{\mathbb{Z}}$, and the extended intermediate language $v^{\mathbb{Z}}$. The syntax of both intermediate languages follow directly from $VPL^{\mathbb{Z}}$ and should be unsurprising. The only important difference from IL is that $ar^{\mathbb{Z}}$ cannot express a \bullet value. This is a purposeful design decision; recall that a \bullet represents a term that has been sent to the base solver. Thus if \bullet were in $ar^{\mathbb{Z}}$ then expressions such as $\bullet + 2$ would be expressible in $ar^{\mathbb{Z}}$, however because all arithmetic formula's require accumulation the only possible result of evaluation/accumulation on arithmetic expressions is either a choice or a symbolic term, not a \bullet . Hence, we syntactically avoid classes bugs by eliding the \bullet value in $ar^{\mathbb{Z}}$.

$$\begin{aligned}
v^{\mathbb{Z}} &::= \bullet \mid t \mid r \mid s \mid \neg v^{\mathbb{Z}} \mid v^{\mathbb{Z}} \otimes v^{\mathbb{Z}} \mid ar^{\mathbb{Z}} \bowtie ar^{\mathbb{Z}} \mid D\langle e, e \rangle \\
ar^{\mathbb{Z}} &::= i \mid r_i \mid s \mid \dagger ar^{\mathbb{Z}} \mid ar^{\mathbb{Z}} \oplus ar^{\mathbb{Z}} \mid D\langle ar, ar \rangle
\end{aligned}$$

Figure 5.6: Extended intermediate language syntax

5.2 Accumulation

The variational SMT version of accumulation is specified in Fig. 5.7 and is a generalized variational fold over the abstract syntax tree of $v^{\mathbb{Z}}$. Just as before accumulation is split into congruence rules over the intermediate languages, computation rules over symbolic values and computation rules for references and choices.

The variational SAT version of accumulation is a specialized form of this version of accumulation. Recall that the only semantic difference between operators is the code emitted to the base solver, hence we generalize the previous version by introducing new notation that dispatches the appropriate operation to emit.

The notation $\otimes[\sigma]$ performs a lookup for the wrapped operator, and $:=$ binds the result of the lookup to a variable. For example, if $\sigma = \wedge$ then A-BOOL-S specializes to A-AND-S where $\underline{\sigma} := \underline{\text{And}}$, and thus the resultant call becomes $\underline{\text{And}}(\Delta_2, s_1, s_2)$. Hence, the rules A-AND-S, and A-OR-S are merely specialized forms of the general rule A-BOOL-S.

Similarly, with the extra notation we collapse the arithmetic and inequality computation rules to A-ARITH-S and A-INEQ-S. The semantics of each rule, besides the operator lookup, remains unchanged; the congruence rules recur into the abstract syntax tree to convert references to symbolic values, choices are skipped over due to A-CHC and A-CHC-I, and plain values are combined with the computation rules A-BOOL-S,

$$\begin{array}{c}
\frac{\text{Var}(\Delta, r) = (\Delta', s)}{(\Delta, r) \mapsto (\Delta', s)} \text{A-REF} \qquad \frac{\text{Var}_i(\Delta, r_i) = (\Delta', s)}{(\Delta, r_i) \mapsto (\Delta', s)} \text{A-REF-I} \\
\\
\frac{(\Delta, v^{\mathbb{Z}}) \mapsto (\Delta', s) \quad \text{Not}(\Delta', s) = (\Delta'', s')}{(\Delta, \neg v^{\mathbb{Z}}) \mapsto (\Delta'', s')} \text{A-NOT-S} \\
\\
\frac{\sigma \in \dagger \quad \dagger[\sigma] := \underline{\sigma} \quad (\Delta, ar^{\mathbb{Z}}) \mapsto (\Delta', s) \quad \underline{\sigma}(\Delta', s) = (\Delta'', s')}{(\Delta, \sigma \ ar^{\mathbb{Z}}) \mapsto (\Delta'', s')} \text{A-UNARY-S} \\
\\

\\
\frac{(\Delta, v_1^{\mathbb{Z}}) \mapsto (\Delta_1, v_1^{\mathbb{Z}'}) \quad (\Delta_1, v_2^{\mathbb{Z}}) \mapsto (\Delta_2, v_2^{\mathbb{Z}'})}{(\Delta, v_1^{\mathbb{Z}} \otimes v_2^{\mathbb{Z}}) \mapsto (\Delta_2, v_1^{\mathbb{Z}'} \otimes v_2^{\mathbb{Z}'})} \text{A-BOOL-V} \\
\\
\frac{(\Delta, ar_1^{\mathbb{Z}}) \mapsto (\Delta_1, ar_1^{\mathbb{Z}'}) \quad (\Delta_1, ar_2^{\mathbb{Z}}) \mapsto (\Delta_2, ar_2^{\mathbb{Z}'})}{(\Delta, ar_1^{\mathbb{Z}} \oplus ar_2^{\mathbb{Z}}) \mapsto (\Delta_2, ar_1^{\mathbb{Z}'} \oplus ar_2^{\mathbb{Z}'})} \text{A-ARITH-V} \\
\\
\frac{(\Delta, ar_1^{\mathbb{Z}}) \mapsto (\Delta_1, ar_1^{\mathbb{Z}'}) \quad (\Delta_1, ar_2^{\mathbb{Z}}) \mapsto (\Delta_2, ar_2^{\mathbb{Z}'})}{(\Delta, ar_1^{\mathbb{Z}} \bowtie ar_2^{\mathbb{Z}}) \mapsto (\Delta_2, ar_1^{\mathbb{Z}'} \bowtie ar_2^{\mathbb{Z}'})} \text{A-INEQ-V}
\end{array}$$

Figure 5.7: Accumulation inference rules

A-ARITH-S, and A-INEQ-S. The only other substantial difference is two new computation rules to handle arithmetic choices and variables, A-CHC-I, and A-REF-I. Both serve the same function as their boolean counterparts A-CHC and A-REF.

In this form it should be plain to see the recipe to further extend accumulation to another background theory. One would add a new computation rules for the new kinds of references and choices, a new computation rule for symbolic references in the theory, and a new congruence rule over the new abstract syntax trees. Extending accumulation with new operators is similarly trivial. Recall the modulus example, to extend accumulation with a modulus operator, assuming the wrapped primitive has been defined, we would only need to add the operator to \oplus syntactic category and create a case such that $mod \in \oplus$ succeeds.

5.3 Evaluation

make into subsection
or paragraph? Only 1
page long...

Evaluation's purpose is to assert symbolic terms in the base solver if it is safe to do so. Thus, the extensions to evaluation are minimal as accumulation is performing the majority of the work in creating the symbolic terms.

Variational SMT evaluation is defined in [Fig. 5.8](#). The only change is the addition of E-INEQ corresponding to the addition of inequalities to VPL. Just as E-OR skips over un-accumulated disjunctions, E-INEQ skips over un-accumulated inequalities as evaluating inside an inequality is unsound in the base solver. Since evaluation calls E-ACC to accumulate relations if E-AND-L, E-AND-R, and E-AND don't apply, variational SMT evaluation simply relies on accumulation to progress. The special cases for conjunctions

$$\begin{array}{c}
\frac{(\Delta, v^{\mathbb{Z}}) \mapsto (\Delta', v^{\mathbb{Z}'}) \quad (\Gamma, \Delta', v^{\mathbb{Z}'}) \mapsto (\Gamma', \Delta'', v^{\mathbb{Z}''})}{(\Gamma, \Delta, v^{\mathbb{Z}}) \mapsto (\Gamma', \Delta'', v^{\mathbb{Z}''})} \text{E-ACC} \quad \frac{\text{Assert}(\Gamma, \Delta, s) = \Gamma'}{(\Gamma, \Delta, s) \mapsto (\Gamma', \Delta, \bullet)} \text{E-SYM} \\
\\

Figure 5.9: Variational SMT zipper context

are maintained in order to sequence evaluation from left to right to take advantage of the behavior of the assertion stack and to propagate accumulation across conjunctions, just as in variational satisfiability evaluation.

5.4 Choice removal

With accumulation and evaluation complete we turn to choice removal. Our strategy is similar to accumulation; we generalize the zipper context over Boolean, arithmetic and inequality relations using the syntactic categories defined in Fig. 5.5. Conceptually, choice removal remains a variational left fold that builds the zipper context until a symbolic value is the focus. at which point rules of the form C- \ast -INL *switch* the fold to process the right child of the relations, and rules of the form C- \ast -INR call accumulation to reduce the relation over symbolic values. We formally specify generalized choice removal in Fig. 5.10. The heart of choice removal remains the same, the rules C-EVAL, C-CHC, C-CHC-T, and C-CHC-Fare reproduced for the new zipper context $z^{\mathbb{Z}}$ but are semantically identical to the specialized versions. The remaining rules are generalized

$$\begin{array}{c}

\end{array}$$

Figure 5.10: Variational SMT choice removal inference rules

versions of the SAT rules to handle each syntactic category the variational solver can process.

For each syntactic category we define three kinds of rules which form a template to extend choice removal to new background theories: First, we have rules which determine what to do when encountering a binary or unary relation for the first time. As a design choice this is defined to proceed into the left child. For example C-NOT, C-BOOL, and C-INEQ initiate the left fold by storing the relation in the zipper and focusing the left child v_l^Z . Second, we define rules which recur down the left child of the relations until a symbolic value results from accumulation. For example, C-INEQ-INL, C-BOOL-INL and C-ARITH-INL all move the focused symbol value s to the zipper context allowing choice removal to proceed to the right children of the same relation. Lastly, we have computation rules which perform the fold on the relation by calling accumulation. For example, C-UNARY-IN, C-ARITH-INR and C-INEQ-INR call accumulation to process the symbolic value and reduce the given relation. In effect, accumulation *encapsulates* the semantics of the relations, evaluation propagates accumulation and performs code generation in the base solver, and choice removal alters the configuration, maintains evaluation contexts, and removes choices introducing new plain terms to the formula.

5.5 Variational SMT models

We have thus far covered accumulation, evaluation, and choice removal. However, to support SMT theories, variational models must be abstract enough to handle values other than Booleans. Functionally, variational SMT models must satisfy several constraints:

the variational SMT model must be more memory efficient than storing all models returned by the solver naively. The variational model must allow users to find satisfying values for a variant. The model must allow users to find all variants in which a variable has a particular value or range of values.

Furthermore, several useful properties of variational models should be maintained: The model is non-variational; the user should not need to understand the choice calculus to understand their results. The model produces results that can be fed into a plain SAT or SMT solver. The model can be built incrementally and without regard to the ordering of results. Variational SAT models guaranteed this last constraint by forming commutative monoid under \vee ; a technique which we cannot replicate for variational SMT models.

To maintain these properties and satisfy the functional requirements, our strategy for variational SMT models is to create a mapping of variables to SMT expressions. By virtue of this strategy, variables are disallowed from changing types across variants and hence disallowed from changing type as the result of a choice. For any variable in the model, we assume the type returned by the base solver is correct, and store the satisfying value in a linked list constructed *if-statements*¹. Specifically, we utilize the function $ite : \mathbb{B} \rightarrow T \rightarrow T$ from the SMTLIB2 standard to construct the list. All variables are initialized as undefined (*Und*) until a value is returned from the base solver for a variant. To ensure the correct value of a variable corresponds to the appropriate variant, we translate the configuration which determines the variant to a variation context, and place the appropriate value in the *then* branch.

¹Also called a church-encoded list

Consider the following variational SMT problem extended with an integer arithmetic theory: $f = ((A\langle i, 13 \rangle - c) < (b + 10)) \rightarrow B\langle a, c > i \rangle$. f contains two unique choices, A , B , and thus represents four variants. In this case, the expression is under-constrained and so each variant will be found satisfiable.

$$\begin{array}{ll}
 i \rightarrow -1 & \\
 c \rightarrow 0 & c \rightarrow 0 \\
 & a \rightarrow \text{F} \\
 b \rightarrow 4 & b \rightarrow 0 \\
 C_{FF} = \{(A, \text{false}), (B, \text{false})\} & C_{FF} = \{(A, \text{false}), (B, \text{true})\} \\
 \\
 i \rightarrow 0 & i \rightarrow -1 \\
 c \rightarrow 0 & c \rightarrow 0 \\
 & a \rightarrow \text{T} \\
 b \rightarrow -10 & b \rightarrow 3 \\
 C_{FT} = \{(A, \text{true}), (B, \text{false})\} & C_{TT} = \{(A, \text{true}), (B, \text{true})\}
 \end{array}$$

Figure 5.11: Possible plain models for variants of f .

Fig. 5.11 show possible plain models for f with the corresponding variational SMT model presented in Fig. 5.12. We've added line breaks to emphasize the *then* and *else* branches of the *ite* SMTLIB2 primitive.

This formulation maintains the functional requirements and desirable properties of the variational SAT models. The variable $_Sat$ is used to track the variants that were found satisfiable, just as in the variational SAT solver. In this case, all variants are satisfiable and thus we have four clauses over dimensions in disjunctive normal form. If a user has a configuration then they only need to perform substitution to determine the value of a variable under that configuration. For example, if the user were interested in the value of i in the $\{(A, \text{T}), (B, \text{T})\}$ variant they would substitute the configuration

$$\begin{aligned}
_Sat &\rightarrow (\neg A \wedge \neg B) \vee (\neg A \wedge B) \vee (A \wedge \neg B) \vee (A \wedge B) \\
i &\rightarrow (ite (A \wedge B) -1 \\
&\quad (ite (A \wedge \neg B) 0 \\
&\quad\quad (ite (\neg A \wedge \neg B) -1 Und))) \\
c &\rightarrow (ite (A \wedge B) 0 \\
&\quad (ite (A \wedge \neg B) 0 \\
&\quad\quad (ite (\neg A \wedge B) 0 \\
&\quad\quad\quad (ite (\neg A \wedge \neg B) 0 Und))) \\
a &\rightarrow (ite (A \wedge B) \top \\
&\quad (ite (\neg A \wedge B) \text{F} Und)) \\
b &\rightarrow (ite (A \wedge B) 3 \\
&\quad (ite (A \wedge \neg B) -10 \\
&\quad\quad (ite (\neg A \wedge B) 0 \\
&\quad\quad\quad (ite (\neg A \wedge \neg B) 4 Und)))
\end{aligned}$$

Figure 5.12: Variational model corresponding to the plain models in [Fig. 5.11](#).

into the result for i and recover 2 from the first *ite* case. To find the variants at which a variable has a value, a user may employ a SMT solver, add the entry for i as a constraint, and query for a model. This specification of variational SMT models does not require knowledge of choice calculus or variation, it is still monoidal—although not a commutative monoid—and can be built in any order as long as there are no duplicate variants; a scenario that is impossible by the property of synchronization on choices.

However, there are some notable differences. Where variational SAT models clearly compressed results by preventing duplicate values with constant variables, the variational SMT model allows for duplicate values, if those values are produced out of order. For example, both models for i and c contain duplicate values. The i model has duplicate -1 and the c model contains duplicate 0. However only one: c is easy to check in $\mathcal{O}(1)$ time; each call to COMBINE could check the last immediate value to prevent

duplicate branches. In contrast, the duplicate -1 's for i occur in variants that are likely to occur with several other plain models between them, namely the models for the C_{TF} and C_{FF} variants. Hence, a check during COMBINE would require $\mathcal{O}(n)$ time, where n is the number of satisfiable variants that i occurs in. While such a case is easily avoided in an implementation by tracking the values a variable has been previously assigned, we provide only a minimum specification and thus leave the details to an implementation. Lastly, the use of *Und* may seem unattractive. While all bindings in the model end with an *Und*, a binding cannot result in an *Und* as that would imply a variant that was found to be satisfiable but was not satisfiable, and hence would be indicative of a bug in the variational solver implementation. Thus mathematically inclined readers may observe that the monoid variational SMT models form corresponds to the free monoid formed by church-encoded lists.

5.6 A complete Variational SMT example

With variational SMT solving formally specified. We present a complete example of solving a variational SMT problem. Consider the query formula

$h = ((1 + \varrho < (i - A\langle k, l \rangle)) \wedge a) \wedge (B\langle c, \neg b \rangle \vee b)$ with two choices parameterized by the dimensions A and B . Derivation of the variational core for h begins with all evaluation and all stores Δ, Γ initialized to \emptyset .

The root of h is \wedge and thus E-AND is the only applicable rule. From E-AND we have $v_1^{\mathbb{Z}} = ((1 + \varrho < (i - A\langle k, l \rangle)) \wedge a)$, and $v_2^{\mathbb{Z}} = (B\langle c, \neg b \rangle \vee b)$. We traverse $v_1^{\mathbb{Z}}$ first, leading to a recursive application of E-AND. We denote recursive levels with a tick

mark: ', thus $v_1^{\mathbb{Z}'} = (1 + 2 < (i - A\langle k, l \rangle))$ is the left child of $v_1^{\mathbb{Z}}$, with $v_2^{\mathbb{Z}'} = a$ as the right child.

The root of $v_1^{\mathbb{Z}'}$ is an inequality, so the only way to progress is to try to accumulate $v_1^{\mathbb{Z}'}$. The accumulation will succeed; in accumulation, only A-INEQ-V can apply as accumulation will be unable to transform the right child of $v_1^{\mathbb{Z}'}$ to a symbolic value due to the presence of a choice. A-INEQ-V will further destruct $v_1^{\mathbb{Z}'}$ to $ar_1^{\mathbb{Z}} = 1 + 2$ and $ar_2^{\mathbb{Z}} = i - A\langle k, l \rangle$. $ar_1^{\mathbb{Z}}$ will be accumulated to a single symbolic value by application of A-ARITH-S and A-REF on the literals 1 and 2 yielding $ar_1^{\mathbb{Z}} = s_{12}$, with store $\Delta = \{(s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$.

Using the resultant store from accumulating $ar_1^{\mathbb{Z}}$, accumulation on $ar_2^{\mathbb{Z}}$ will yield the term $s_i - A\langle k, l \rangle$. The variable i will be accumulated to a symbolic value with A-REF and the choice will be passed over by A-CHC. Thus we have the accumulated result for $v_1^{\mathbb{Z}'}$ as the intermediate term $v_1^{\mathbb{Z}}{}_{acc} = s_{12} < (s_i - A\langle k, l \rangle)$ with store $\Delta = \{(i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$.

With the left child of $v_1^{\mathbb{Z}'}$ accumulated, E-AND attempts to continue evaluation on the right child and will succeed. Notice that this is a special case as the root of $v_1^{\mathbb{Z}}$ is \wedge and so is the root of h . Thus, $v_2^{\mathbb{Z}}$ will transform a to a symbolic value through accumulation using the previous store and assert the symbolic value in the base solver with E-SYM. The resulting intermediate term will be $s_{12} < (s_i - A\langle k, l \rangle) \wedge \bullet$, with stores $\Gamma = \{s_a\}$, $\Delta = \{(a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$ and will be reduce to the final intermediate result $v_1^{\mathbb{Z}}{}_{core} = s_{12} < (s_i - A\langle k, l \rangle)$ with the same stores via application of E-AND-R.

We have now returned back to the top level call to E-AND with a result for the left

child and populated stores. Evaluation will proceed on the right child $v_2^{\mathbb{Z}}$. $v_2^{\mathbb{Z}}$'s root is a disjunction, and thus to proceed evaluation switched to accumulation by applying E-ACC. The accumulation is straightforward; the left child is the choice $B\langle c, \neg b \rangle$ and is returned by A-CHC. The right child is a single variable, and thus is translated to the symbolic value s_b . Thus we have the final result for $v_2^{\mathbb{Z}}$, $v_2^{\mathbb{Z}}{}_{core} = B\langle c, \neg b \rangle \vee s_b$ and the variational core of h , $h_{core} = s_{12} < (s_i - A\langle k, l \rangle) \wedge (B\langle c, \neg b \rangle \vee s_b)$ with stores $\Gamma = \{s_a\}$, $\Delta = \{(b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$.

With the variational core derived we can begin choice removal. We assume an empty configuration for the remainder of the example. The exact semantics of a vc is implementation specific. For example, our prototype variational SAT solver pre-populates the configuration with a generated configuration based on the user vc . In contrast, the prototype variational SMT solver checks the dimensions assignments of true or false in C-CHC are valid with respect to the vc , if not then the variant is skipped.

Choice removal begins with the variational core in the focus and an evaluation context $z^{\mathbb{Z}} = \top$, because h_{core} 's root is \wedge only C-BOOL applies moving $s_{12} < (s_i - A\langle k, l \rangle)$ into the focus and storing the right child in the context: $z^{\mathbb{Z}} = \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$. With $s_{12} < (s_i - A\langle k, l \rangle)$ as the focus, the only applicable rule is C-INEQ due to $<$ at the root of the focus. C-INEQ again recurs left, focusing on the sub-term s_{12} with context $z^{\mathbb{Z}} = \cdot < (s_i - A\langle k, l \rangle) :: \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$ which states that s_{12} exists in the left child of an inequality which also exists in the left child of a conjunction.

We have arrived at the base case with a symbolic value is in focus, and the immediate parent in the evaluation context is an inequality. To proceed we need to *switch* to begin processing the right child of the inequality; thus we must apply C-INEQ-INL.

C-INEQ-INL swaps the symbolic with the un-processed right child held in the context, hence we have $(s_i - A\langle k, l \rangle)$ in focus with context $z^{\mathbb{Z}} = s_{12} < \cdot :: \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$. $-$ is a previously unseen relation, when an new relation is found choice removal will recur into the left child. In this case $- \in \oplus$ and so C-ARITH applies. C-ARITH moves s_i into the focus and extend the evaluation context to $z^{\mathbb{Z}} = \cdot - A\langle k, l \rangle :: s_{12} < \cdot :: \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$.

With s_i in the focus we've arrived at another base case, only this time when the switch occurs a choice will be in focus. The switch is performed by C-ARITH-INL and yields $A\langle k, l \rangle$ as the focus with context $z^{\mathbb{Z}} = s_i - \cdot :: s_{12} < \cdot :: \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$. Now we the heart of choice removal applies, because we have $C = \emptyset$, the only applicable rule with a choice in the focus is C-CHC. C-CHC creates two recursive calls, one for each alternative using *the same context*, thus we'll have $C = \{(A, \text{true})\}$, with focus k , and context $z^{\mathbb{Z}} = s_i - \cdot :: s_{12} < \cdot :: \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$.

For the remainder of the example we'll continue with only true alternatives; the other

make sure this isn't a
type error

variants follow similar paths. Accumulation is called on the introduced plain terms, converting k to s_k and extending the accumulation store to

$$\Delta = \{(k, s_k), (b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}.$$

With a symbolic value in the focus, and with the context already switched to the right child we have come to a sequence of base cases which perform the folds, in this case C-ARITH-INR applies. C-ARITH-INR calls accumulation on $s_i - s_k$. $s_i - s_k$ has not yet been observed in accumulation and thus the new symbolic value s_{ik} will be generated. This yields s_{ik} in the focus, with $\Delta = \{(s_i - s_k, s_{ik}), (k, s_k), (b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$, and $z^{\mathbb{Z}} = s_{12} < \cdot :: \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$.

With s_{ik} in the focus we have yet another base case which consumes some context, only this time we consume the inequality using C-INEQ-INR. C-INEQ-INR calls accumulation on $s_{12} < s_{ik}$, similar to the previous call over – this call produces a new symbolic value and extends the accumulation store. Hence, we'll have s_{12ik} in the focus, with $\Delta = \{(s_{12} < s_{ik}, s_{12ik}), (s_i - s_k, s_{ik}), (k, s_k), (b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$, and $z^{\mathbb{Z}} = \cdot \wedge (B\langle c, \neg b \rangle \vee s_b) :: \top$ as the evaluation context. With a symbolic value in the focus, and a context indicating the left child of a relation, choice removal switches to process the right alternative. The relation in this case is \wedge and so C-BOOL-INL applies to execute the switch yielding $B\langle c, \neg b \rangle \vee s_b$ in the focus, and $z^{\mathbb{Z}} = s_{12ik} \wedge \cdot :: \top$. \vee is a relation that is previously unseen, and thus C-BOOL recurs into its left child yielding the choice $B\langle c, \neg b \rangle$ in the focus and

$z^{\mathbb{Z}} = \cdot \vee s_b :: s_{12ik} \wedge \cdot :: \top$ as the context.

We have arrived at the second choice. $B \notin \text{dom}(C)$ and thus only C-CHC applies. Following the true alternative for B , accumulation is called on c yielding s_c in the focus, with $C = \{(B, \text{true}), (A, \text{true})\}$, $\Delta = \{(c, s_c), (s_{12} < s_{ik}, s_{12ik}), (s_i - s_k, s_{ik}), (k, s_k), (b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$, and $z^{\mathbb{Z}} = \cdot \vee s_b :: s_{12ik} \wedge \cdot :: \top$. All that is left is a switch and then to complete the fold with the symbolic values. C-BOOL-INL switches the context placing s_b in the focus and yielding $z^{\mathbb{Z}} = s_c \vee \cdot :: s_{12ik} \wedge \cdot :: \top$, which will be followed by C-BOOL-INR to disjunct s_c and s_b using accumulation. The resulting term will have s_{bc} in the focus, $\Delta = \{(s_c \vee s_b, s_{cb}), (c, s_c), (s_{12} < s_{ik}, s_{12ik}), (s_i - s_k, s_{ik}), (k, s_k), (b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$, and $z^{\mathbb{Z}} = s_{12ik} \wedge \cdot :: \top$, which leaves only one more reduction until model generation. C-BOOL-INR applies again to conjunct the last two symbolic values, yielding $z^{\mathbb{Z}} =$

\top, s_{12ikbc} in the focus and $\Delta = \{(s_{12ik} \wedge s_{bc}, s_{12ikbc}), (s_c \vee s_b, s_{cb}), (c, s_c), (s_{12} < s_{ik}, s_{12ik}), (s_i - s_k, s_{ik}), (k, s_k), (b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$.

Thus we have reached the variant parameterized by $C = \{(B, \text{true}), (A, \text{true})\}$ C-EVAL applies due to $z^{\mathbb{Z}} = \top$ and the symbolic value in the focus, E-SYM will yields

- with $z^{\mathbb{Z}} = \top$, indicating that it is safe to query a model for this variant from the base solver. Due to the two application of C-CHCthree other variants will be found during back tracking beginning with the dimension used in the most recent application. In this case that is the dimension B , and thus the next variant that will be found is parameterized by $C = \{(B, \text{false}), (A, \text{true})\}$ with context $z^{\mathbb{Z}} = \cdot \vee s_b :: s_{12ik} \wedge \cdot :: \top$ and $\Delta = \{(c, s_c), (s_{12} < s_{ik}, s_{12ik}), (s_i - s_k, s_{ik}), (k, s_k), (b, s_b), (a, s_a), (i, s_i), (s_1 + s_2, s_{12}), (2, s_2), (1, s_1)\}$.

5.7 Variational SMT Arrays

With variational SMT solving fully specified we can reflect on the generalization recipe from the previous sections. Say we desired to add the SMT background for REALS. Doing so would follow the straightforward recipe demonstrated with INTS: From the SMTLIB2 standard we have a set of primitive operators, we would define wrapped primitive versions for each operator. Using these wrapped operators we would define new cases for accumulation and a base case for evaluation indicating that the new operator requires accumulation. Then we would add the new domain to the syntactic categories in Fig. 5.5. Choice removal would be extended with three new rules, a rule to begin the processing of the left child of the relation, a rule to switch from the left child to the

right only when a symbolic value is in the focus, and a rule that performs the fold by combining two symbolic values and thus consuming some of the context.

In essence, we have a recipe for a generalized variational folding algorithm over binary relations, that forces reuse of shared terms and is applied to the domain of SAT and SMT solvers. Recall that a symbolic value is a sequence of statements in the base solver. Thus, another way to view our generalized folding algorithm is as a compiler from the language of variational SAT or SMT to plain SMTLIB2 script. The stages of the compiler in this interpretation are straightforward: We parse a variational SAT or SMT problem to a abstract syntax tree in an intermediate language. The intermediate language enables optimization passes and is easier to work with than the object language. Accumulation and evaluation produce a variational core which can be seen as another, further reduced core language, or as a syntax object which encapsulates the variational aspects of the input. The core language is then operated upon by choice removal which deterministically produces the variant syntax objects. Code generation is spread across generation of symbolic values in accumulation, assertion of constraints in evaluation, and calls to `PUSH` or `POP` during choice removal, specifically during C-CHC.

The exact ordering of the operations in the base solver, or the ordering of code generation, is implementation specific. In the prototype solvers that we have produced and will discuss further in the next chapter, code generation that corresponds to generating symbolic values occurs when the symbolic value becomes known to Δ . When a configuration occurs the `PUSH/POP` calls encapsulate the operator the choice was nested in and any new symbolic values which result from the configuration. This ensures sharing of terms that are in the same assertion levels. For example, consider the case of s_{12} from

[Section 5.6](#), s_{12} will be shared once for each variant because it is plain, thus the code

which defines it must occur *before* a PUSH and POP call:

```

(declare-const  $s_1$  Int)           ;; literal declarations
(declare-const  $s_2$  Int)
(declare-fun  $s_{12}$  () Int
  (+  $s_1$   $s_2$ ))
(push)                               ;; push for true alternative of A
:

```

Similarly for terms such as s_{ik} which will be shared twice but are not plain; because i was transformed into a symbolic before the choice was configured its declaration still occurs outside the PUSH/POP block. In contrast, k is parameterized by a choice and thus its declaration occurs inside a PUSH/POP block:

```

(declare-const  $s_1$  Int)           ;; literal declarations
(declare-const  $s_2$  Int)
(declare-fun  $s_{12}$  () Int
  (+  $s_1$   $s_2$ ))
:
(declare-const  $s_i$  Int)           ;; i is declared
(push)                               ;; push for true alternative of A
(declare-const  $s_k$  Int)
(declare-fun  $s_{ik}$  () Int
  (<  $s_i$   $s_k$ ))
:

```

In this case the ordering of symbolic value generation forced s_k to be inside the PUSH call so that it is removed from the local scope of the solver after a POP and thus the boundaries between alternatives do not leak information. Notice that the inference rules in [Section 5.2](#), [Section 5.3](#) and [Section 5.4](#) guarantee this behavior because symbolic value creation is ordered according to levels of variation. For example, plain terms are level 0 as no configuration has happened. In a sense they are globally scoped and thus become

symbolic values or \bullet 's first. It is only after a configuration occurs from C-CHC that more plain terms are introduced. When a configuration occurs a new PUSH/POP block is entered, and thus any calls to accumulation which occur inside it occur inside that block in the base solver and correspond to level 1. Furthermore, the level is propagated by the $D \in C$ check in C-CHC-T and C-CHC-F.

To demonstrate the generality of this design we now consider the case of adding SMT arrays. To add SMT arrays we treat arrays as a new kind of relation. By treating them like any other relation, we take advantage of the aforementioned ordering behavior and offload the hard work to choice removal. SMT arrays are defined by two operations (*store* $a\ i\ e$) and (*select* $a\ i$), where a is a variable representing the array, i is an index into the array, and e is an element of the array. Each operation must exist inside a boolean constraint to propagate information about the array, for example (*store* $a\ 2\ b$) leaves a unconstrained, while $a \equiv (\text{store } a\ 2\ b)$ adds a constraint that forces position 2 to store b in a . Similarly, *select* must exist in a constraint, e.g., $x \equiv (\text{select } a\ 2)$ will add a constraint which sets x to b .

Assume that we restrict i to only INT, using the recipe above we would wrap these operations, add new rules to accumulation to accumulate anything in the a , i , or e positions and then extend $z^{\mathbb{Z}}$ such that a context could be captured wherever choices may occur. For example we might have: Which is verbose but would work. Now consider a formula which contains a nested choice in an arithmetic expression in the element slot of *select* but not store: $f = (a \equiv (\text{store } a\ 2\ (i - A\langle k, l \rangle))) \wedge (i \equiv \text{select } a\ 2) \wedge (i \equiv l)$. The conjunctions indicate separate statements in SMTLIB2 due to the behavior of the assertion stack. The formula is noteworthy because both the *select* and $i \equiv l$ call are

$$\begin{array}{lcl}
z^{\mathbb{Z}} & ::= & \top \\
& | & \neg \cdot :: z^{\mathbb{Z}} \\
& | & \dagger \cdot :: z^{\mathbb{Z}} \\
& | & \cdot \otimes v^{\mathbb{Z}} :: z^{\mathbb{Z}} \\
& | & s \otimes \cdot :: z^{\mathbb{Z}} \\
& | & \cdot \oplus v^{\mathbb{Z}} :: z^{\mathbb{Z}} \\
& | & s \oplus \cdot :: z^{\mathbb{Z}} \\
& | & \cdot \boxtimes v^{\mathbb{Z}} :: z^{\mathbb{Z}} \\
& | & s \boxtimes \cdot :: z^{\mathbb{Z}} \\
& | & (\text{store } \cdot \ s \ s) :: z^{\mathbb{Z}} \\
& | & (\text{store } s \ \cdot \ s) :: z^{\mathbb{Z}} \\
& | & (\text{store } s \ s \ \cdot) :: z^{\mathbb{Z}} \\
& | & (\text{select } \cdot \ s) :: z^{\mathbb{Z}} \\
& | & (\text{select } s \ \cdot) :: z^{\mathbb{Z}}
\end{array}$$

plain and thus will be processed by evaluation/accumulation *before* choice removal via the E-AND-L and E-AND-R. This may seem problematic as calling a *select* before a *store* in other paradigms would lead to an error. However this will not be the case, consider the compiled SMTLIB2 script for f :

```

(declare-const  $s_a$  (Array Int Int))           ;; variable declarations
(declare-const  $s_i$  Int)
(declare-const  $s_l$  Int)
(declare-const  $s_2$  Int)
(declare-fun  $s_{sel}$  () Int                       ;; select
  (=  $s_i$  (select  $s_a$   $s_2$ )))
(declare-fun  $s_{il}$  () Int                       ;; equivalency constraint
  (=  $s_i$   $s_l$ ))
(assert  $s_{sel}$ )
(assert  $s_{il}$ )
(push)                                           ;; push for true alternative of A
(declare-const  $s_k$  Int)
(declare-fun  $s_{ik}$  () Int
  (-  $s_i$   $s_k$ ))
(assert (=  $s_a$  (store  $s_a$  ( $s_2$ ) ( $s_{ik}$ ))))

```

```

(check-sat)
(get-model)                ;; plain model for true alternative
(pop)
(push)                     ;; push for false alternative of A
(declare-fun  $s_{il}$  () Int
  (-  $s_i$   $s_l$ ))
(assert (=  $s_a$  (store  $s_a$  ( $s_2$ ) ( $s_{il}$ )))
(check-sat)
(get-model)                ;; plain model for false alternative
(pop)

```

We see that evaluation/accumulation did find the plain *select* and $i \equiv l$ constraints and assert them before the choice is processed. However, because constraints in the base solver can be unordered—due to the implicit conjunction of all assertions in an assertion level—the out of order *select* and constraint $i \equiv l$ are not problematic. Furthermore, we see that the SMTLIB2 snippet has desirable properties: every plain or variational term that can be shared, such as l and i , is shared. When a PUSH/POP block is entered the block is as small as possible, thus sharing is maximized as much as possible. Due to the symbolic values generated by accumulation/evaluation, variation does not spread past the immediate relation and thus other relations do not suffer from variational infection.

We have demonstrated the generality of our approach by extensions with the differing domains of arithmetic over integers and arrays. Key to the approach is the indirection with symbolic values, and the use of a zipper to construct a generalized variational folding algorithm over any unary, binary, or ternary relation. Thus, with just what has been presented here we can support the rest of the core theories in SMTLIB2 using the aforementioned extension recipe. We return to this point in [Chapter 7](#) when we discuss the implications for a variational logic programming language.

Chapter 6: Case Studies

We have formalized variational SMT and SAT solving. However, we have yet to investigate the performance of our methods. Recall from [Chapter 1](#) that one of the motivating reasons for a variational solver was the idea that if we only compute shared terms once, then we should observe a speedup in runtime performance when solving sets of related acsat problems. In this chapter, we investigate and verify these claims.

Assessing the performance of SAT and SMT solvers is notoriously difficult [\[44\]](#) because it highly depends on the input to the SAT or SMT solver. The issue is related to the hardness of the input problem, where hardness is a ratio of clauses in the SAT or SMT problem to the number of variables. If we have many clauses and not many variables then the problem is over-constrained and it is easy to show UNSAT, however if there are not many clauses but many variables then the problem is under-constrained and it is easy to show SAT.

Thus to investigate, we construct a prototype variational solver, VSAT in the Haskell programming language [\[48\]](#) and quantitatively compare it to incremental and non-incremental SAT solving. To assess the prototype in realistic conditions we reuse real-world data from a previous study by Nieke et al. [\[66\]](#) from the SPL community.

Before we describe the datasets we first introduce some terminology from the SPL community. A software product-line is an instance of variational software; or more formally it is a set of software-intensive systems that share a common, managed set of

features satisfying the specific needs of a particular market segment or mission and that are developed from a common set of core assets in a prescribed way.

A good example of a software product-line is the Linux kernel [81]. The Linux kernel is a set of core assets which devise an operating system, but the assets are parameterized by *features* which, in this case, are the Boolean conditions of conditional-compilation statements such as `#ifdefs`. To select the particular kind of kernel to build, the Linux kernel uses the `KConfig` [27] tool to enable or disable features and thus specify the exact kernel to build. The set of features and their dependencies which determine the product, or in this case determine the kernel that is built is call a *feature model*[50].

It is common to express feature models as a SAT formula where variables are features, and dependencies are expressed using logical connectives. Thus, reasoning about feature models with a SAT solver is an active sub-field in software product-lines [13, 41, 12, 80]. In this domain, if a SAT is returned from the solver then the resulting model is an assignment of features which specifies a viable product. If an UNSAT is returned than no viable product exists given the constraints on the feature model for the software product-line.

6.1 Experimental Methodology

We must distinguish between concepts in the application domain, such as kinds of analysis on feature models e.g., a void or core analysis, and concepts in the solver domain, such as a query or choice. In general, we focus on the solver domain as it is our primary concern.

Nieke et al. provides two datasets¹, *automotive02* and *financialServicesI* which encode the evolution histories of two feature models as propositional formulas. Thus variants in our analysis correspond to snapshots of a feature models over time. We refer to these as the *auto* dataset, and *fin* dataset for the remainder of this chapter. For example, a variant of the *auto* dataset is a C_2 formula which encodes a feature model at time 0, and another variant encodes *the same* feature model at time 2, where $0 < 2$. We use the phrase *version variant* to refer to variants that are versions or snapshots of a sound feature model in the application domain.

We assess the performance characteristics VSAT by attempting to answer the following research questions.

RQ1 How does variational solving scale as variation increases?

RQ2 What is the impact of base solvers on performance?

RQ3 What is the impact of sharing on performance?

RQ4 What is the cost of solving a plain formula on VSAT?

To investigate **RQ1** and **RQ2**, we consider all variants of the VPL formulas constructed for each dataset, rather than just the version variants that are of interest in the application domain. This allows us to better evaluate how VSAT scales to accommodate variability. For **RQ3**, we hypothesize that VSAT will get faster as sharing increases, which would validate our method of deriving a variational core. To investigate this, we restrict the analysis to consecutive version variants (i.e., consecutive monthly snapshots

¹see <https://gitlab.com/evolutionexplanation/evolutionexplanation>

of a feature model), and observe performance as sharing is left uncontrolled. Finally, **RQ4** provides insight on the overhead incurred by variational solving, which we investigate by inputting each version variant as a propositional logic formula rather than a single variational formula for each solver used in **RQ2** and **RQ1**.

6.1.1 Data Description and Encoding

Nieke et al.’s formulas collapse sets of C_2 formulas to a single formula using implications on an SMT variable that represents a moment in time. A two-pass process was used to translate Nieke et al.’s formulas into VPL—one pass to parse to an internal representation and another to detect and convert Nieke et al.’s temporal ranges to choices, nesting the implied clauses into the true alternative. The two-pass process conserves Nieke et al.’s ordering of plain terms and encoding. The two datasets differ in important ways. The *auto* dataset encodes four monthly snapshots while the *fin* dataset encodes ten. Hence, the *auto*’s query formula represents 16 variants, while the *fin* query formula represents 1,024 variants. For **RQ3** and **RQ4**, we construct several *vc*’s to restrict the analysis to version variants. The *vc*s range from ones that enable only one version variant (for **RQ4**): $vc_{auto_V_1} = (V_1 \wedge \neg V_2 \wedge \neg V_3 \wedge \neg V_4)$ to *vc*s that enable only consecutive version variants (for **RQ3**): $vc_{auto_V12} = V_1 \vee V_2$.

For **RQ4** we decouple performance from the number of variants by performing an initial pass over the query formula to replace choices representing non-consecutive versions variants (e.g. a variational formula which represents V_1 and V_2 but not V_1 and V_3) with their false alternatives (which contain the value \top). Then we construct a *vc* to forbid

non-version variants. As an example, the *auto* dataset, yields three data points by this process, the change from versions V_1 to V_2 , V_2 to V_3 , and V_3 to V_4 . All results presented for **RQ3** were calculated using the z3 [29] SAT solver.

Measuring Performance To answer our research questions, we construct four different solving algorithms using our prototype tool. We use the notation $i\text{formula}_i \rightarrow i\text{solver}_i$ to describe, for each algorithm, whether the query formulas and solver are plain (p) or variational (v), respectively. The algorithms are: the baseline, $p \rightarrow p$, which runs plain formulas on a plain solver; variational case, $v \rightarrow v$, which runs a variational formula on the variational solver; the overhead case, $p \rightarrow v$, which runs plain formulas on the variational solver; and the typical case, $v \rightarrow p$, which runs the variational formula, variant by variant, on a plain solver. Inputs for each algorithm are constructed by configuring the query formula, thus ensuring that the same variation context is used across algorithms.

We construct the $p \rightarrow p$ algorithm by configuring the query formula to its variants *before* benchmarking begins. These formulas are then sent to the base solver one-by-one, with the solver begin shut down and initialized between runs, thus preventing the solver from maintaining any learned information. The $p \rightarrow v$ case corresponds to **RQ4** and elucidates the potential overhead of solving a plain query on a variational solver. We perform the same pre-processing as the $p \rightarrow p$ case but send each plain formula to VSAT instead. This provides insight into the cost incurred by the reduction engine. For $v \rightarrow p$, we configure the query formula to retrieve variants *during* benchmarking. Each formula is sent to the base solver *with* the solver maintaining information between queries. This gives insight into the overhead incurred by configuring a variational formula, and the

benefits of the internal caching in the base solver. Notable, this case keeps the base solver running, performing each call in incremental mode, thus this case corresponds to the typical use of an incremental solver in applications that utilize incremental SAT solvers.

We construct a variational model for all algorithms since it is unclear how to combine plain models, and since the storage of plain models is an orthogonal concern to performance, we sought to keep convolved variables constant.

Unless specified, all results are a bootstrapped statistical average representing numerous raw measurements.² For **RQ2** we repeat **RQ1** with four different base solvers: z3 [29], cvc4 [8], yices [30] and boolector [16], each of which called through the widely used Haskell library [35]. To assess **RQ2** we perform a Kruskal-Wallis test [68] followed by a pairwise Wilcoxon test [88] with Holm-Bonferroni p-value correction [46] in the R programming language [70] v4.0.3 and assume a 5% significance level. For **RQ3**, we similarly normalize the data to the baseline ($v \rightarrow p$), fit a linear model, and statistically assess differences by repeating the aforementioned statistical tests. For **RQ4**, we retrieve the raw measurements from the bootstrapped average and assess statistical differences identically to **RQ3** but do not fit any models to the data. Furthermore, the variational input is nuanced for **RQ4** as each data point is on a variant, which is necessarily plain. Thus, **RQ4** is a special case; for **RQ4** $v \rightarrow v$ inputs the variational formula but utilizes a variant context to restrict the solver to the version variant. $v \rightarrow p$ performs configuration

²Using v0.2.5 of the gauge [69] library and v8.6 of the sbv [35] library with solver seeds set to 1729. All data was collected on a desktop running NixOS 20.09, with an AMD Ryzen 7 2700X CPU @ 4.0GHz, 32GB RAM. We used stack lts-15.7 (GHC 8.8.3) and tested with RTS options “-qg” which enables parallel garbage collection in the Haskell runtime.

Figure 6.1: Most models found to be unsatisfiable. Only a small portion of features ever flipped to T.

to configure for the version variant and then runs the variant on a base solver during benchmarking. All results, including variational models and statistical analysis scripts, are available online.³

6.2 Results and Discussion

The datasets yielded dissimilar query formulas: the *auto* query formula consisted of 4,212 choice terms (not including terms in a choice’s alternatives), and 26,808 plain terms. In contrast, *fin* had 3,809 choice terms, and 1,441 plain terms. Thus *fin* had larger changes between product line versions. Fig. 6.1 shows the ratio of unsatisfiable models to total plain models, and the ratio of constant features for each product line version

³<https://github.com/lambda-land/VSat-Papers/tree/master/EMSE2021>

(represented by variant count). For both datasets the number of satisfiable models decreased as new versions were considered, and the majority of features in each model never flipped from their initialized value F to T. Thus, the variational model is likely a compressed version of the set of plain models. Compression metrics were not calculated as this is an orthogonal concern to the performance of variational satisfiability solving.

Variational models permit product analyses without a SAT solver. [Fig. 6.1](#) shows such a purely syntactic analysis: counting disjunct clauses in the variational model as a representation of satisfiable plain models. We believe post-hoc analyses such as this may be useful to feature modelers as they direct attention to impactful versions of the feature model. For example, the change from V_7 to V_8 (128 to 256 Variants) of *fin* clearly constrained the feature model as the number of unsatisfiable models increased from 50% to 80%.

The experiment required 7 days, 6 hours and 21 minutes to complete. Due to the amount of time required to generate the data, we limited the number of raw measurements to 3. Thus, each data point presented in our results is a bootstrapped average of 3 raw measurements. In contrast, the conference version of this work used 56 raw measurements per data point. This experiment quadruples the run time of the conference version, because we repeat the experiment with four base solvers. Thus we restrict the sampling as the experiment was not feasible with the previous rate of sampling. Our results agree with our former work even with the reduced sampling.

RQ1: Performance of Variational Solving as Variation Scales The VSAT tool outperforms other algorithms as the count of variants to solve increases for every base

Figure 6.2: (Auto) RQ1: performance as variants increase per base solver. $v \rightarrow v$ shows a speedup of 2.8–3.5x for the *auto* dataset depending on base solver.

DataSet	Boolector	CVC4	Yices	Z3	Boolector	CVC4	Yices	Z3
<i>auto</i>	3.29	3.51	3.20	2.62	623.0	738.6	623.7	862.0
<i>fin</i>	2.44	2.51	2.50	2.16	788.8	1026.6	729.2	884.2

(a) Speedup by solver for the most variational case; 16 variants for *auto*, 1024 for *fin*.

(b) Time [s] to solve with $v \rightarrow v$ by solver.

Table 6.1: Time to solve and speedup of most variational case by solver.

Figure 6.3: (Financial) RQ1: performance as variants increase per base solver. $v \rightarrow v$ shows a speedup of 2.4–3.2x for the *fin* dataset depending on the base solver. Overlapping x-axis labels elided.

solver. Fig. 6.2 shows the time to solve the query formula as variants increase from 2 to 16 for the *auto* dataset for each solver. Similarly Fig. 6.3 shows time to solve by base solver for the *fin* dataset.

For the *auto* dataset, variational solving is faster with an average speedup of 2.60x. For the most variational case (16 variants) the greatest speedup was found to be 3.5x with cvc4. The *fin* dataset shows an average speedup of 4.70x⁴. For the most variational case (1024 variants), cvc4 also showed the greatest speedup at 2.51x. We find that $v \rightarrow v$ is statistically different from every other algorithm with p-values of 2.77×10^{-4} ($v \rightarrow p$), 1.06×10^{-2} ($p \rightarrow p$), and 1.92×10^{-2} ($p \rightarrow v$) for *auto* and 1.62×10^{-5} ($v \rightarrow p$), 1.92×10^{-5} ($p \rightarrow p$), and 1.70×10^{-4} ($p \rightarrow v$) for *fin*.

VSAT outperforms the other algorithms because the variational core caches plain terms, thereby preventing the re-evaluation of these terms for each variant. By this data, we observed a constant factor speedup. Thus, variational solving still grows linearly in the number of variants being solved.

RQ2: Performance Impact of Base Solver In the conference version of this work, we cited that all of our results were dependent on z3 as a threat to validity. In this research question we address that threat. From **RQ1** we determined that $v \rightarrow v$ is faster than the baseline algorithms and that the difference is statistically significant. We observe from Fig. 6.2 and Fig. 6.3 that the $v \rightarrow v$ algorithm is robust across every tested base solver and $v \rightarrow v$ produced reasonable results with each base solver.

We summarize our results in Table 6.1. Notable yices was consistently the most

⁴Due to extreme outliers (10x–15.1x speedup) from yices when solving 2–32 variants.

performant base solver for all algorithms and all test cases. For $v \rightarrow v$ yices demonstrates not only a high degree of speedup but also a reduction of 238.3 seconds, and 132.8 seconds, in run time from z3 for the most variational case of *auto* and *fin*. Thus, yices is an attractive target for the base solver of future prototype variational SAT solvers.

Cvc4 is also noteworthy; cvc4 benefited the most from $v \rightarrow v$ for both datasets with a speedup 3.51x (*auto*) and 2.51 (*fin*). The cvc4 case is interesting as it implies that a base solver which shows poor performance with in the typical use case ($v \rightarrow p$; SAT calls occur in an incremental context, and solver is kept alive) may greatly benefit from the variational solving algorithm we’ve presented. Although the exact reasons behind this behavior will be particular to the base solver, these results imply that our use case (i.e., heavily exercising the incremental code paths) is peculiar and thus selecting a solver based on only its typical performance may not be representative of its performance in this use case.

RQ3: Performance Impact of Plain Terms We hypothesize that the ratio of plain terms to total terms should increase the variational solver’s performance. Specifically, we hypothesize that as sharing grows, the query formula’s variational core is further reduced. We observe this behavior using the z3 data in [Fig. 6.4](#). Both $v \rightarrow v$ and $p \rightarrow p$ showed a statistically significant fit to a linear model. Furthermore, only $v \rightarrow v$ was found to be statistically different from $p \rightarrow p$ and $p \rightarrow v$ with p-values of 6.95×10^{-3} and 4.44×10^{-6} thus confirming that sharing positively correlates to speedups for variational solving in these datasets.

This result is evidence that a dataset’s sharing ratio is an important factor in the

Figure 6.4: RQ3: Performance as a function of plain ratio. We observe that sharing positively correlates to speedup only for $v \rightarrow v$, where $\% \text{ SpeedUp} = \frac{\text{Algorithm}}{v \rightarrow p}$.

performance of a variational SAT solver, as we hypothesized. When the sharing ratio is high, the reduction engine produces a smaller variational core. With a smaller variational core, more reuse of plain terms occurs and thus computational time is saved in the base solver. Hence, an avenue of future work is to leverage the laws of the variational logic to automatically refactor input formulas to increase sharing. The consequences of this observation will be particular to the application domain. For software product lines this means that any method to increase sharing between product line versions or the representative SAT problems is desirable; this may be smaller changes with respect to the entire feature model, more frequent snapshots of the feature model, or syntactic manipulations to mitigate the occurrence of new features.

(a) (Auto) RQ4: Overhead of $v \rightarrow v$ on plain formulas. We observe that $v \rightarrow v$ incurs an average slowdown of 9% for *auto*, when solving a version variant.

(b) (Financial) RQ4: Overhead of $v \rightarrow v$ on plain formulas. We observe that $v \rightarrow v$ incurs an average slowdown of 75% for the *fin* dataset, when solving a version variant.

RQ4: Overhead of a Plain Query on VSAT Fig. 6.5a and Fig. 6.5b displays the bootstrapped averages of each version variant, for each algorithm, and base solver for the *auto*, and *fin* datasets, respectively. Given RQ2, and the composition of *fin*, we expect VSAT to show slowdowns for *fin*. This is observed in Fig. 6.5b and is statistically significant for all versions. For *auto*, only the V_1 version variant showed a significant difference between the overhead case, $p \rightarrow v$, and $v \rightarrow v$, and between the overhead case $p \rightarrow v$, and the typical case $v \rightarrow p$. Notably, $v \rightarrow v$ did not differ from the typical case, $v \rightarrow p$. Fig. 6.5a suggests statistically significant differences for other versions but omits variance, hence the discrepancy between the plot and statistical tests. That $p \rightarrow v$ was statistically different for V_1 suggests particular formulas may not respond well to the reduction engine, although the exact slowdown will be dependent on the SAT problem.

Threats to Validity Our results are subject to several threats to validity. Notably, we are unable to make absolute performance claims because our study, with only two product lines, may not be representative. To mitigate this we reused real-world data from Nieke et al.’s previous study [66] and chose dissimilar product lines. We inherit encoding-based threats to validity by reusing Nieke et al.’s formulas but ensured each algorithm experienced identical ordering of plain terms as described in ???. Furthermore our results, and our prototype solver are based on the widely used Haskell library sbv. However, we believe this is a likely to be a common implementation strategy for a variational solver (i.e., a solver built using a library rather than a foreign function interface, similar to tools built on top of sat4j [54]) it is nonetheless a threat to validity as our prototype directly depends on this library. To mitigate this threat we maintained the

same version of sbv throughout the experiment, employed its interface to interoperate for each base solver, and enforced the same code paths through the library.

We have evinced the scalability claim with RQ1, and shown the translation and automation of incremental solving in [Chapter 4](#). However, our results depend on a VPL formula as input. We believe that VPL formulas can be incrementally and automatically constructed in practice, as described in [Chapter 3](#), as new variants occur or become known. However, assessing the challenges of VPL construction is left to future work.

In this paper, we do not provide a proof of the soundness of our methods. We mitigate this threat in several ways: we performed property-based testing [\[26\]](#) on our prototype and verified that a satisfiable variant was found to be satisfiable across all algorithms. In addition, we define a property that ensures that for each plain model p , found with $p \rightarrow v$, $v \rightarrow p$, and $p \rightarrow p$, an identical model p' was found by substituting p on the variational model returned from VSAT. We performed the property-based tests with 3,000 generated VPL formulas, finding no counter-examples.

Chapter 7: Related Work

Related work has been discussed throughout the previous sections. This section collects related work that was not previously covered. To my knowledge, this work is the first to translate the specific ideas of a nanopass architecture, and a variational compiler, to the SAT/SMT domains. Furthermore, at time of this writing this work is the first to investigate variational concurrency.

This work is most similar to [84], which also constructs a SAT solver that exploits shared terms and prevents redundant computation. However, the projects differ in important ways. Visser et al.’s solver is oriented for program analysis and does not use incremental SAT solving. Rather, it uses heuristics to find canonical forms of sliced programs, and caches solver results on these canonical forms in a key-value store [53]. In contrast, variational SAT solving is domain agnostic, solves SAT problems expressed in VPL, returns a variational model, and uses incremental SAT solving.

Variational SAT solving is the latest in a line of work that uses the choice calculus to investigate variation as a computational phenomena. The choice calculus has been successfully applied to diverse areas of computer science, such as databases [4, 5], graphics [36], data structures [63, 86, 77, 39], type systems [18, 19, 23, 24], error messages [22, 20, 23, 21], and now satisfiability solving. Our use of choices is similar to the concept of *facets* [6] and *faceted execution* [73, 64, 7], which have been successfully applied to information-flow security and policy-agnostic programming.

The use of compiler optimization techniques in SAT solvers is not novel, for example common subexpression elimination (CSE) and variable elimination has been successfully implemented in SAT solvers[31, 67]. Other pre-processing techniques such as removing blocked clauses [45], and detecting autarkies [57] have been very successful at automatically increasing performance of the SAT or SMT solver. From this perspective, our use of choices is a pre-processing technique to speed up incremental solving over sets of related problems.

Some solvers such as z3 [29], allow users to program the heuristics used by the solver to find choose efficient solving techniques, z3 in particular calls these constructs *strategies*. Strategies are thus similar to many optimizing compiler techniques [1], only applied to the SAT domain

Chapter 8: Conclusion

SAT and SMT solvers are ubiquitous and powerful tools in computer science and software engineering. Incremental SAT and SMT provide an interface that supports solving many related problems efficiently. However, the interface could be automated and improved.

The goal of this thesis is to explore the design and architecture of a variational satisfiability solver that automates and improves on the incremental SAT interface. Through the application of the choice calculus the interface can be automated for satisfiability problems, the solver interaction can be formalized and made asynchronous, and the solver is able to directly express variation in a problem domain.

The thesis will present a complete approach to variational satisfiability and satisfiability modulo theory solving based on incremental solving. It will include a method to automatically encode a set of Boolean formulae into a variational propositional formula. A method for detecting the difficulty of solving such a variational propositional formula. A data set suitable for future research in the SAT, SPL and variation research communities. A variational satisfiability solver, an asynchronous variational satisfiable modulo theory solver and a proof of variational preservation.
